68. The quantity $nt$ in Equations 37.17 and 37.18 is called the optical path length corresponding to the geometrical distance $t$ and is analogous to the quantity $\delta$ in Equation 37.1, the path difference. The optical path length is proportional to $n$ because a larger index of refraction shortens the wavelength, so more cycles of a wave fit into a particular geometrical distance. (a) Assume a mixture of corn syrup and water is prepared in a tank, with its index of refraction $n$ increasing uniformly from 1.33 at $y = 20.0$ cm at the top to 1.90 at $y = 0$. Write the index of refraction $n(y)$ as a function of $y$. 
problems 1159

73. Both sides of a uniform film that has index of refraction \( n \) and thickness \( d \) are in contact with air. For normal incidence of light, an intensity minimum is observed in the reflected light at \( \lambda_1 \) and an intensity maximum is observed at \( \lambda_2 \), where \( \lambda_1 > \lambda_2 \). (a) Assuming no intensity minima are observed between \( \lambda_1 \) and \( \lambda_2 \), find an expression for the integer \( m \) in Equations 37.17 and 37.18 in terms of the wavelengths \( \lambda_1 \) and \( \lambda_2 \). (b) Assuming \( n = 1.40 \), \( \lambda_1 = 500 \text{ nm} \), and \( \lambda_2 = 370 \text{ nm} \), determine the best estimate for the thickness of the film.

75. Monochromatic light of wavelength 620 nm passes through a very narrow slit S and then strikes a screen in which are two parallel slits, S1 and S2, as shown in Figure P37.75. Slit S1 is directly in line with S and at a distance of \( L = 1.20 \text{ m} \) away from S, whereas S2 is displaced a distance \( d \) to one side. The light is detected at point P on a second screen, equidistant from S1 and S2. When either slit S1 or S2 is open, equal light intensities are measured at point P. When both slits are open, the intensity is three times larger. Find the minimum possible value for the slit separation \( d \).

76. A plano-convex lens having a radius of curvature of \( r = 4.00 \text{ m} \) is placed on a concave glass surface whose radius of curvature is \( R = 12.0 \text{ m} \) as shown in Figure P37.76. Assuming 500-nm light is incident normal to the flat surface of the lens, determine the radius of the 100th bright ring.
When plane light waves pass through a small aperture in an opaque barrier, the aperture acts as if it were a point source of light, with waves entering the shadow region behind the barrier. This phenomenon, known as diffraction, was first mentioned in Section 35.3, and can be described only with a wave model for light. In this chapter, we investigate the features of the diffraction pattern that occurs when the light from the aperture is allowed to fall upon a screen.

In Chapter 34, we learned that electromagnetic waves are transverse. That is, the electric and magnetic field vectors associated with electromagnetic waves are perpendicular to the direction of wave propagation. In this chapter, we show that under certain conditions these transverse waves with electric field vectors in all possible transverse directions can be polarized in various ways. In other words, only certain directions of the electric field vectors are present in the polarized wave.

38.1 Introduction to Diffraction Patterns

In Sections 35.3 and 37.1, we discussed that light of wavelength comparable to or larger than the width of a slit spreads out in all forward directions upon passing through the slit. This phenomenon is called diffraction. When light passes through a narrow slit, it spreads beyond the narrow path defined by the slit into regions that would be in shadow if light traveled in straight lines. Other waves, such as sound waves and water waves, also have this property of spreading when passing through apertures or by sharp edges.
You might expect that the light passing through a small opening would simply result in a broad region of light on a screen due to the spreading of the light as it passes through the opening. We find something more interesting, however. A diffraction pattern consisting of light and dark areas is observed, somewhat similar to the interference patterns discussed earlier. For example, when a narrow slit is placed between a distant light source (or a laser beam) and a screen, the light produces a diffraction pattern like that shown in Figure 38.1. The pattern consists of a broad, intense central band (called the central maximum) flanked by a series of narrower, less intense additional bands (called side maxima or secondary maxima) and a series of intervening dark bands (or minima). Figure 38.2 shows a diffraction pattern associated with light passing by the edge of an object. Again we see bright and dark fringes, which is reminiscent of an interference pattern.

Figure 38.3 shows a diffraction pattern associated with the shadow of a penny. A bright spot occurs at the center, and circular fringes extend outward from the shadow’s edge. We can explain the central bright spot by using the wave theory of light, which predicts constructive interference at this point. From the viewpoint of ray optics (in which light is viewed as rays traveling in straight lines), we expect the center of the shadow to be dark because that part of the viewing screen is completely shielded by the penny.

Shortly before the central bright spot was first observed, one of the supporters of ray optics, Simeon Poisson, argued that if Augustin Fresnel’s wave theory of light were valid, a central bright spot should be observed in the shadow of a circular object illuminated by a point source of light. To Poisson’s astonishment, the spot was observed by Dominique Arago shortly thereafter. Therefore, Poisson’s prediction reinforced the wave theory rather than disproving it.

### 38.2 Diffraction Patterns from Narrow Slits

Let’s consider a common situation, that of light passing through a narrow opening modeled as a slit and projected onto a screen. To simplify our analysis, we assume the observing screen is far from the slit and the rays reaching the screen are approximately parallel. (This situation can also be achieved experimentally by using a converging lens to focus the parallel rays on a nearby screen.) In this model, the pattern on the screen is called a *Fraunhofer diffraction pattern*.¹

Figure 38.4a (page 1162) shows light entering a single slit from the left and diffracting as it propagates toward a screen. Figure 38.4b shows the fringe structure of

¹If the screen is brought close to the slit (and no lens is used), the pattern is a *Fresnel diffraction pattern*. The Fresnel pattern is more difficult to analyze, so we shall restrict our discussion to Fraunhofer diffraction.
Figure 38.4 (a) Geometry for analyzing the Fraunhofer diffraction pattern of a single slit. (Drawing not to scale.) (b) Simulation of a single-slit Fraunhofer diffraction pattern.

Pitfall Prevention 38.1 Diffraction Versus Diffraction Pattern Diffraction refers to the general behavior of waves spreading out as they pass through a slit. We used diffraction in explaining the existence of an interference pattern in Chapter 37. A diffraction pattern is actually a misnomer, but is deeply entrenched in the language of physics. The diffraction pattern seen on a screen when a single slit is illuminated is actually another interference pattern. The interference is between parts of the incident light illuminating different regions of the slit.

Figure 38.5 Paths of light rays that encounter a narrow slit of width \(a\) and diffract toward a screen in the direction described by angle \(\theta\) (not to scale).

A Fraunhofer diffraction pattern. A bright fringe is observed along the axis at \(\theta = 0\), with alternating dark and bright fringes on each side of the central bright fringe.

Until now, we have assumed slits are point sources of light. In this section, we abandon that assumption and see how the finite width of slits is the basis for understanding Fraunhofer diffraction. We can explain some important features of this phenomenon by examining waves coming from various portions of the slit as shown in Figure 38.5. According to Huygens’s principle, each portion of the slit acts as a source of light waves. Hence, light from one portion of the slit can interfere with light from another portion, and the resultant light intensity on a viewing screen depends on the direction \(\theta\). Based on this analysis, we recognize that a diffraction pattern is actually an interference pattern in which the different sources of light are different portions of the single slit! Therefore, the diffraction patterns we discuss in this chapter are applications of the waves in interference analysis model.

To analyze the diffraction pattern, let’s divide the slit into two halves as shown in Figure 38.5. Keeping in mind that all the waves are in phase as they leave the slit, consider rays 1 and 3. As these two rays travel toward a viewing screen far to the right of the figure, ray 1 travels farther than ray 3 by an amount equal to the path difference \((a/2) \sin \theta\), where \(a\) is the width of the slit. Similarly, the path difference between rays 2 and 4 is also \((a/2) \sin \theta\), as is that between rays 3 and 5. If this path difference is exactly half a wavelength (corresponding to a phase difference of 180°), the pairs of waves cancel each other and destructive interference results. This cancellation occurs for any two rays that originate at points separated by half the slit width because the phase difference between two such points is 180°. Therefore, waves from the upper half of the slit interfere destructively with waves from the lower half when

\[
\frac{a}{2} \sin \theta = \frac{\lambda}{2}
\]

or, if we consider waves at angle \(\theta\) both above the dashed line in Figure 38.5 and below,

\[
\sin \theta = \pm \frac{\lambda}{a}
\]

Dividing the slit into four equal parts and using similar reasoning, we find that the viewing screen is also dark when

\[
\sin \theta = \pm \frac{\lambda}{2a}
\]

Likewise, dividing the slit into six equal parts shows that darkness occurs on the screen when

\[
\sin \theta = \pm \frac{\lambda}{3a}
\]
Therefore, the general condition for destructive interference is

\[ \sin \theta_{\text{dark}} = \frac{m \lambda}{a} \]

where \( m \) is an integer. This equation gives the values of \( \theta_{\text{dark}} \) for which the diffraction pattern has zero light intensity, that is, when a dark fringe is formed. It tells us nothing, however, about the variation in light intensity along the screen. The general features of the intensity distribution are shown in Figure 38.4. A broad, central bright fringe is observed; this fringe is flanked by much weaker bright fringes alternating with dark fringes. The various dark fringes occur at the values of \( \theta_{\text{dark}} \) that satisfy Equation 38.1. Each bright-fringe peak lies approximately halfway between its bordering dark-fringe minima. Notice that the central bright maximum is twice as wide as the secondary maxima. There is no central dark fringe, represented by the absence of \( m = 0 \) in Equation 38.1.

Quick Quiz 38.1 Suppose the slit width in Figure 38.4 is made half as wide. Does the central bright fringe (a) become wider, (b) remain the same, or (c) become narrower?

Example 38.1 Where Are the Dark Fringes? AM

Light of wavelength 580 nm is incident on a slit having a width of 0.300 mm. The viewing screen is 2.00 m from the slit. Find the width of the central bright fringe.

SOLUTION

Conceptualize Based on the problem statement, we imagine a single-slit diffraction pattern similar to that in Figure 38.4. We categorize this example as a straightforward application of our discussion of single-slit diffraction patterns, which comes from the waves in interference analysis model.

Analyze Evaluate Equation 38.1 for the two dark fringes that flank the central bright fringe, which correspond to \( m = \pm 1 \):

Let \( y \) represent the vertical position along the viewing screen in Figure 38.4a, measured from the point on the screen directly behind the slit. Then, \( \tan \theta_{\text{dark}} = y/L \), where the subscript 1 refers to the first dark fringe. Because \( \theta_{\text{dark}} \) is very small, we can use the approximation \( \sin \theta_{\text{dark}} = \tan \theta_{\text{dark}} \); therefore, \( y_1 = L \sin \theta_{\text{dark}} \).

The width of the central bright fringe is twice the absolute value of \( y_1 \):

\[ 2|y_1| = 2L \sin \theta_{\text{dark}} = 2|\pm L \frac{\lambda}{a}| = 2L \frac{\lambda}{a} = 2(2.00 \text{ m}) \frac{580 \times 10^{-9} \text{ m}}{0.300 \times 10^{-3} \text{ m}} = 7.73 \times 10^{-4} \text{ m} = 7.73 \text{ mm} \]

Finalize Notice that this value is much greater than the width of the slit. Let’s explore below what happens if we change the slit width.

What If? What if the slit width is increased by an order of magnitude to 3.00 mm? What happens to the diffraction pattern?

Answer Based on Equation 38.1, we expect that the angles at which the dark bands appear will decrease as \( a \) increases. Therefore, the diffraction pattern narrows.

Repeat the calculation with the larger slit width:

\[ 2|y_1| = 2L \frac{\lambda}{a} = 2(2.00 \text{ m}) \frac{580 \times 10^{-9} \text{ m}}{3.00 \times 10^{-3} \text{ m}} = 7.73 \times 10^{-4} \text{ m} = 0.773 \text{ mm} \]

Notice that this result is smaller than the width of the slit. In general, for large values of \( a \), the various maxima and minima are so closely spaced that only a large, central bright area resembling the geometric image of the slit is observed. This concept is very important in the performance of optical instruments such as telescopes.
Intensity of Single-Slit Diffraction Patterns

Analysis of the intensity variation in a diffraction pattern from a single slit of width \( a \) shows that the intensity is given by

\[
I = I_{\text{max}} \left( \frac{\sin \left( \frac{\pi a \sin \theta}{\lambda} \right)}{\sin \left( \frac{\pi a \sin \theta}{\lambda} \right)} \right)^2
\]  

(38.2)

where \( I_{\text{max}} \) is the intensity at \( \theta = 0 \) (the central maximum) and \( \lambda \) is the wavelength of light used to illuminate the slit. This expression shows that minima occur when

\[
\frac{\pi a \sin \theta_{\text{dark}}}{\lambda} = m\pi
\]

or

\[
\sin \theta_{\text{dark}} = m \frac{\lambda}{a} \quad m = \pm 1, \pm 2, \pm 3, \ldots
\]

in agreement with Equation 38.1.

Figure 38.6a represents a plot of the intensity in the single-slit pattern as given by Equation 38.2, and Figure 38.6b is a simulation of a single-slit Fraunhofer diffraction pattern. Notice that most of the light intensity is concentrated in the central bright fringe.

Intensity of Two-Slit Diffraction Patterns

When more than one slit is present, we must consider not only diffraction patterns due to the individual slits but also the interference patterns due to the waves coming from different slits. Notice the curved dashed lines in Figure 37.7 in Chapter 37, which indicate a decrease in intensity of the interference maxima as \( \theta \) increases. This decrease is due to a diffraction pattern. The interference patterns in that figure are located entirely within the central bright fringe of the diffraction pattern, so the only hint of the diffraction pattern we see is the falloff in intensity toward the outside of the pattern. To determine the effects of both two-slit interference and a single-slit diffraction pattern from each slit from a wider viewpoint than that in Figure 37.7, we combine Equations 37.14 and 38.2:

\[
I = I_{\text{max}} \cos^2 \left( \frac{\pi d \sin \theta}{\lambda} \right) \left( \frac{\sin \left( \frac{\pi a \sin \theta}{\lambda} \right)}{\sin \left( \frac{\pi a \sin \theta}{\lambda} \right)} \right)^2
\]  

(38.3)

Although this expression looks complicated, it merely represents the single-slit diffraction pattern (the factor in square brackets) acting as an "envelope" for a two-slit interference pattern (the cosine-squared factor) as shown in Figure 38.7. The broken...
blue curve in Figure 38.7 represents the factor in square brackets in Equation 38.3. The cosine-squared factor by itself would give a series of peaks all with the same height as the highest peak of the red-brown curve in Figure 38.7. Because of the effect of the square-bracket factor, however, these peaks vary in height as shown.

Equation 37.2 indicates the conditions for interference maxima as \( d \sin \theta = m\lambda \), where \( d \) is the distance between the two slits. Equation 38.1 specifies that the first diffraction minimum occurs when \( a \sin \theta = \lambda \), where \( a \) is the slit width. Dividing Equation 37.2 by Equation 38.1 (with \( m = 1 \)) allows us to determine which interference maximum coincides with the first diffraction minimum:

\[
\frac{d \sin \theta}{a \sin \theta} = \frac{m\lambda}{\lambda} = m
\]

(38.4)

In Figure 38.7, \( d/a = 18 \, \mu m/3.0 \, \mu m = 6 \). Therefore, the sixth interference maximum (if we count the central maximum as \( m = 0 \)) is aligned with the first diffraction minimum and is dark.

Quick Quiz 38.2 Consider the central peak in the diffraction envelope in Figure 38.7 and look closely at the horizontal scale. Suppose the wavelength of the light is changed to 450 nm. What happens to this central peak? (a) The width of the peak decreases, and the number of interference fringes it encloses decreases. (b) The width of the peak decreases, and the number of interference fringes it encloses increases. (c) The width of the peak decreases, and the number of interference fringes it encloses remains the same. (d) The width of the peak increases, and the number of interference fringes it encloses decreases. (e) The width of the peak increases, and the number of interference fringes it encloses increases. (f) The width of the peak increases, and the number of interference fringes it encloses remains the same. (g) The width of the peak remains the same, and the number of interference fringes it encloses decreases. (h) The width of the peak remains the same, and the number of interference fringes it encloses increases. (i) The width of the peak remains the same, and the number of interference fringes it encloses remains the same.
### 38.3 Resolution of Single-Slit and Circular Apertures

The ability of optical systems to distinguish between closely spaced objects is limited because of the wave nature of light. To understand this limitation, consider Figure 38.8, which shows two light sources far from a narrow slit of width $a$. The sources can be two noncoherent point sources $S_1$ and $S_2$; for example, they could be two distant stars. If no interference occurred between light passing through different parts of the slit, two distinct bright spots (or images) would be observed on the viewing screen. Because of such interference, however, each source is imaged as a bright central region flanked by weaker bright and dark fringes, a diffraction pattern. What is observed on the screen is the sum of two diffraction patterns: one from $S_1$ and the other from $S_2$.

If the two sources are far enough apart to keep their central maxima from overlapping as in Figure 38.8a, their images can be distinguished and are said to be resolved. If the sources are close together as in Figure 38.8b, however, the two central maxima overlap and the images are not resolved. To determine whether two images are resolved, the following condition is often used:

When the central maximum of one image falls on the first minimum of another image, the images are said to be just resolved. This limiting condition of resolution is known as **Rayleigh’s criterion**.

From Rayleigh’s criterion, we can determine the minimum angular separation $\theta_{\text{min}}$ subtended by the sources at the slit in Figure 38.8 for which the images are just resolved. Equation 38.1 indicates that the first minimum in a single-slit diffraction pattern occurs at the angle for which

$$\sin \theta = \frac{\lambda}{a}$$

where $a$ is the width of the slit. According to Rayleigh’s criterion, this expression gives the smallest angular separation for which the two images are resolved. Because $\lambda \ll a$ in most situations, $\sin \theta$ is small and we can use the approximation $\sin \theta \approx \theta$. Therefore, the limiting angle of resolution for a slit of width $a$ is

$$\theta_{\text{min}} = \frac{\lambda}{a} \quad (38.5)$$

where $\theta_{\text{min}}$ is expressed in radians. Hence, the angle subtended by the two sources at the slit must be greater than $\lambda/a$ if the images are to be resolved.

Many optical systems use circular apertures rather than slits. The diffraction pattern of a circular aperture as shown in the photographs of Figure 38.9 consists of
Resolution of Single-Slit and Circular Apertures

a central circular bright disk surrounded by progressively fainter bright and dark rings. Figure 38.9 shows diffraction patterns for three situations in which light from two point sources passes through a circular aperture. When the sources are far apart, their images are well resolved (Fig. 38.9a). When the angular separation of the sources satisfies Rayleigh’s criterion, the images are just resolved (Fig. 38.9b). Finally, when the sources are close together, the images are said to be unresolved (Fig. 38.9c) and the pattern looks like that of a single source.

Analysis shows that the limiting angle of resolution of the circular aperture is

\[ \theta_{\text{min}} = \frac{1.22 \lambda}{D} \]  

where \( D \) is the diameter of the aperture. This expression is similar to Equation 38.5 except for the factor 1.22, which arises from a mathematical analysis of diffraction from the circular aperture.

Quick Quiz 38.3 Cat’s eyes have pupils that can be modeled as vertical slits. At night, would cats be more successful in resolving (a) headlights on a distant car or (b) vertically separated lights on the mast of a distant boat?

Quick Quiz 38.4 Suppose you are observing a binary star with a telescope and are having difficulty resolving the two stars. You decide to use a colored filter to maximize the resolution. (A filter of a given color transmits only that color of light.) What color filter should you choose? (a) blue (b) green (c) yellow (d) red

Example 38.2 Resolution of the Eye

Light of wavelength 500 nm, near the center of the visible spectrum, enters a human eye. Although pupil diameter varies from person to person, let’s estimate a daytime diameter of 2 mm.

(A) Estimate the limiting angle of resolution for this eye, assuming its resolution is limited only by diffraction.

Solution

Conceptualize Identify the pupil of the eye as the aperture through which the light travels. Light passing through this small aperture causes diffraction patterns to occur on the retina.

Categorize We determine the result using equations developed in this section, so we categorize this example as a substitution problem.

continued
Use Equation 38.6, taking \( \lambda = 500 \text{ nm} \) and \( D = 2 \text{ mm} \):

\[
\theta_{\text{min}} = 1.22 \frac{\lambda}{D} = 1.22 \left( \frac{5.00 \times 10^{-7} \text{ m}}{2 \times 10^{-3} \text{ m}} \right)
\]

\[
= 5 \times 10^{-4} \text{ rad} = 1 \text{ min of arc}
\]

**SOLUTION**

Noting that \( \theta_{\text{min}} \) is small, find \( d \):

\[
\sin \theta_{\text{min}} = \frac{d}{L} \rightarrow d = L \theta_{\text{min}}
\]

Substitute numerical values:

\[
d = (25 \text{ cm})(3 \times 10^{-4} \text{ rad}) = 8 \times 10^{-3} \text{ cm}
\]

This result is approximately equal to the thickness of a human hair.

**Example 38.3 Resolution of a Telescope**

Each of the two telescopes at the Keck Observatory on the dormant Mauna Kea volcano in Hawaii has an effective diameter of 10 m. What is its limiting angle of resolution for 600-nm light?

**SOLUTION**

**Conceptualize** Identify the aperture through which the light travels as the opening of the telescope. Light passing through this aperture causes diffraction patterns to occur in the final image.

**Categorize** We determine the result using equations developed in this section, so we categorize this example as a substitution problem.

Use Equation 38.6, taking \( \lambda = 6.00 \times 10^{-7} \text{ m} \) and \( D = 10 \text{ m} \):

\[
\theta_{\text{min}} = 1.22 \frac{\lambda}{D} = 1.22 \left( \frac{6.00 \times 10^{-7} \text{ m}}{10 \text{ m}} \right)
\]

\[
= 7.3 \times 10^{-8} \text{ rad} = 0.015 \text{ s of arc}
\]

Any two stars that subtend an angle greater than or equal to this value are resolved (if atmospheric conditions are ideal).

**What If?** What if we consider radio telescopes? They are much larger in diameter than optical telescopes, but do they have better angular resolutions than optical telescopes? For example, the radio telescope at Arecibo, Puerto Rico, has a diameter of 305 m and is designed to detect radio waves of 0.75-m wavelength. How does its resolution compare with that of one of the Keck telescopes?

**Answer** The increase in diameter might suggest that radio telescopes would have better resolution than a Keck telescope, but Equation 38.6 shows that \( \theta_{\text{min}} \) depends on both diameter and wavelength. Calculating the minimum angle of resolution for the radio telescope, we find

\[
\theta_{\text{min}} = 1.22 \frac{\lambda}{D} = 1.22 \left( \frac{0.75 \text{ m}}{305 \text{ m}} \right)
\]

\[
= 3.0 \times 10^{-3} \text{ rad} \approx 10 \text{ min of arc}
\]

This limiting angle of resolution is measured in minutes of arc rather than the seconds of arc for the optical telescope. Therefore, the change in wavelength more than compensates for the increase in diameter. The limiting angle of resolution for the Arecibo radio telescope is more than 40 000 times larger (that is, worse) than the Keck minimum.
A telescope such as the one discussed in Example 38.3 can never reach its diffraction limit because the limiting angle of resolution is always set by atmospheric blurring at optical wavelengths. This seeing limit is usually about 1 s of arc and is never smaller than about 0.1 s of arc. The atmospheric blurring is caused by variations in index of refraction with temperature variations in the air. This blurring is one reason for the superiority of photographs from orbiting telescopes, which view celestial objects from a position above the atmosphere.

As an example of the effects of atmospheric blurring, consider telescopic images of Pluto and its moon, Charon. Figure 38.11a, an image taken in 1978, represents the discovery of Charon. In this photograph, taken from an Earth-based telescope, atmospheric turbulence causes the image of Charon to appear only as a bump on the edge of Pluto. In comparison, Figure 38.11b shows a photograph taken from the Hubble Space Telescope. Without the problems of atmospheric turbulence, Pluto and its moon are clearly resolved.

38.4 The Diffraction Grating

The diffraction grating, a useful device for analyzing light sources, consists of a large number of equally spaced parallel slits. A transmission grating can be made by cutting parallel grooves on a glass plate with a precision ruling machine. The spaces between the grooves are transparent to the light and hence act as separate slits. A reflection grating can be made by cutting parallel grooves on the surface of a reflective material. The reflection of light from the spaces between the grooves is specular, and the reflection from the grooves cut into the material is diffuse. Therefore, the spaces between the grooves act as parallel sources of reflected light like the slits in a transmission grating. Current technology can produce gratings that have very small slit spacings. For example, a typical grating ruled with 5000 grooves/cm has a slit spacing \( d = (1/5000) \text{ cm} = 2.00 \times 10^{-4} \text{ cm} \).

A section of a diffraction grating is illustrated in Figure 38.12 (page 1170). A plane wave is incident from the left, normal to the plane of the grating. The pattern observed on the screen far to the right of the grating is the result of the combined effects of interference and diffraction. Each slit produces diffraction, and the diffracted beams interfere with one another to produce the final pattern.

The waves from all slits are in phase as they leave the slits. For an arbitrary direction \( \theta \) measured from the horizontal, however, the waves must travel different path lengths before reaching the screen. Notice in Figure 38.12 that the path difference \( \delta \) between rays from any two adjacent slits is equal to \( d \sin \theta \). If this path difference equals one wavelength or some integral multiple of a wavelength, waves from all slits are in phase at the screen and a bright fringe is observed. Therefore, the condition for maxima in the interference pattern at the angle \( \theta_{\text{bright}} \) is

\[
d \sin \theta_{\text{bright}} = m\lambda \quad m = 0, \pm 1, \pm 2, \pm 3, \ldots
\]  

(38.7)
We can use this expression to calculate the wavelength if we know the grating spacing $d$ and the angle $\theta_{\text{bright}}$. If the incident radiation contains several wavelengths, the $m$th-order maximum for each wavelength occurs at a specific angle. All wavelengths are seen at $\theta = 0$, corresponding to $m = 0$, the zeroth-order maximum. The first-order maximum ($m = 1$) is observed at an angle that satisfies the relation $\sin \theta_{\text{bright}} = \lambda / d$, the second-order maximum ($m = 2$) is observed at a larger angle $\theta_{\text{bright}}$, and so on. For the small values of $d$ typical in a diffraction grating, the angles $\theta_{\text{bright}}$ are large, as we see in Example 38.5.

The intensity distribution for a diffraction grating obtained with the use of a monochromatic source is shown in Figure 38.13. Notice the sharpness of the principal maxima and the broadness of the dark areas compared with the broad bright fringes characteristic of the two-slit interference pattern (see Fig. 37.6). You should also review Figure 37.7, which shows that the width of the intensity maxima decreases as the number of slits increases. Because the principal maxima are so sharp, they are much brighter than two-slit interference maxima.

Quick Quiz 38.5 Ultraviolet light of wavelength 350 nm is incident on a diffraction grating with slit spacing $d$ and forms an interference pattern on a screen a distance $L$ away. The angular positions $\theta_{\text{bright}}$ of the interference maxima are large. The locations of the bright fringes are marked on the screen. Now red light of wavelength 700 nm is used with a diffraction grating to form another diffraction pattern on the screen. Will the bright fringes of this pattern be located at the marks on the screen if (a) the screen is moved to a distance $2L$ from the grating, (b) the screen is moved to a distance $L/2$ from the grating, (c) the grating is replaced with one of slit spacing $2d$, (d) the grating is replaced with one of slit spacing $d/2$, or (e) nothing is changed?

Conceptual Example 38.4 A Compact Disc Is a Diffraction Grating

Light reflected from the surface of a compact disc is multicolored as shown in Figure 38.14. The colors and their intensities depend on the orientation of the CD relative to the eye and relative to the light source. Explain how that works.

Solution

The surface of a CD has a spiral grooved track (with adjacent grooves having a separation on
the order of 1 μm). Therefore, the surface acts as a reflection grating. The light reflecting from the regions between these closely spaced grooves interferes constructively only in certain directions that depend on the wavelength and the direction of the incident light. Any section of the CD serves as a diffraction grating for white light, sending different colors in different directions. The different colors you see upon viewing one section change when the light source, the CD, or you change position. This change in position causes the angle of incidence or the angle of the diffracted light to be altered.

### Example 38.5  The Orders of a Diffraction Grating

Monochromatic light from a helium–neon laser (λ = 632.8 nm) is incident normally on a diffraction grating containing 6000 grooves per centimeter. Find the angles at which the first- and second-order maxima are observed.

**Solution**

**Conceptualize** Study Figure 38.12 and imagine that the light coming from the left originates from the helium–neon laser. Let’s evaluate the possible values of the angle θ for constructive interference.

**Categorize** We determine results using equations developed in this section, so we categorize this example as a substitution problem.

Calculate the slit separation as the inverse of the number of grooves per centimeter:

\[ d = \frac{1}{6000} \text{ cm} = 1.667 \times 10^{-4} \text{ cm} = 1.667 \text{ nm} \]

Solve Equation 38.7 for \( \sin \theta \) and substitute numerical values for the first-order maximum (\( m = 1 \)) to find \( \theta_1 \):

\[ \sin \theta_1 = \frac{(1) \lambda}{d} = \frac{632.8 \text{ nm}}{1.667 \text{ nm}} = 0.379 \]

\[ \theta_1 = 22.31° \]

Repeat for the second-order maximum (\( m = 2 \)):

\[ \sin \theta_2 = \frac{(2) \lambda}{d} = \frac{2(632.8 \text{ nm})}{1.667 \text{ nm}} = 0.759 \]

\[ \theta_2 = 49.41° \]

**WHAT IF?** What if you looked for the third-order maximum? Would you find it?

**Answer** For \( m = 3 \), we find \( \sin \theta_3 = 1.139 \). Because \( \sin \theta \) cannot exceed unity, this result does not represent a realistic solution. Hence, only zeroth-, first-, and second-order maxima can be observed for this situation.

### Applications of Diffraction Gratings

A schematic drawing of a simple apparatus used to measure angles in a diffraction pattern is shown in Figure 38.15 (page 1172). This apparatus is a **diffraction grating spectrometer**. The light to be analyzed passes through a slit, and a collimated beam of light is incident on the grating. The diffracted light leaves the grating at angles that satisfy Equation 38.7, and a telescope is used to view the image of the slit. The wavelength can be determined by measuring the precise angles at which the images of the slit appear for the various orders.

The spectrometer is a useful tool in **atomic spectroscopy**, in which the light from an atom is analyzed to find the wavelength components. These wavelength components can be used to identify the atom. We shall investigate atomic spectra in Chapter 42 of the extended version of this text.

Another application of diffraction gratings is the **grating light valve** (GLV), which competes in some video display applications with the digital micromirror devices (DMDs) discussed in Section 35.4. A GLV is a silicon microchip fitted with an array
Chapter 38  Diffraction Patterns and Polarization

of parallel silicon nitride ribbons coated with a thin layer of aluminum (Fig. 38.16). Each ribbon is approximately 20 \( \mu \text{m} \) long and 5 \( \mu \text{m} \) wide and is separated from the silicon substrate by an air gap on the order of 100 nm. With no voltage applied, all ribbons are at the same level. In this situation, the array of ribbons acts as a flat surface, specularly reflecting incident light.

When a voltage is applied between a ribbon and the electrode on the silicon substrate, an electric force pulls the ribbon downward, closer to the substrate. Alternate ribbons can be pulled down, while those in between remain in an elevated configuration. As a result, the array of ribbons acts as a diffraction grating such that the constructive interference for a particular wavelength of light can be directed toward a screen or other optical display system. If one uses three such devices—one each for red, blue, and green light—full-color display is possible.

In addition to its use in video display, the GLV has found applications in laser optical navigation sensor technology, computer-to-plate commercial printing, and other types of imaging.

Another interesting application of diffraction gratings is holography, the production of three-dimensional images of objects. The physics of holography was developed by Dennis Gabor (1900–1979) in 1948 and resulted in the Nobel Prize in Physics for Gabor in 1971. The requirement of coherent light for holography delayed the realization of holographic images from Gabor’s work until the development of lasers in the 1960s. Figure 38.17 shows a single hologram viewed from two different positions and the three-dimensional character of its image. Notice in particular the difference in the view through the magnifying glass in Figures 38.17a and 38.17b.

Figure 38.18 shows how a hologram is made. Light from the laser is split into two parts by a half-silvered mirror at \( B \). One part of the beam reflects off the object to be photographed and strikes an ordinary photographic film. The other half of the beam is diverged by lens \( L_2 \), reflects from mirrors \( M_1 \) and \( M_2 \), and finally
strikes the film. The two beams overlap to form an extremely complicated interference pattern on the film. Such an interference pattern can be produced only if the phase relationship of the two waves is constant throughout the exposure of the film. This condition is met by illuminating the scene with light coming through a pinhole or with coherent laser radiation. The hologram records not only the intensity of the light scattered from the object (as in a conventional photograph), but also the phase difference between the reference beam and the beam scattered from the object. Because of this phase difference, an interference pattern is formed that produces an image in which all three-dimensional information available from the perspective of any point on the hologram is preserved.

In a normal photographic image, a lens is used to focus the image so that each point on the object corresponds to a single point on the photograph. Notice that there is no lens used in Figure 38.18 to focus the light onto the film. Therefore, light from each point on the object reaches all points on the film. As a result, each region of the photographic film on which the hologram is recorded contains information about all illuminated points on the object, which leads to a remarkable result: if a small section of the hologram is cut from the film, the complete image can be formed from the small piece! (The quality of the image is reduced, but the entire image is present.)

A hologram is best viewed by allowing coherent light to pass through the developed film as one looks back along the direction from which the beam comes. The interference pattern on the film acts as a diffraction grating. Figure 38.19 shows two rays of light striking and passing through the film. For each ray, the $m = 0$ and $m = \pm 1$ rays in the diffraction pattern are shown emerging from the right side of the film. The $m = +1$ rays converge to form a real image of the scene, which is not the image that is normally viewed. By extending the light rays corresponding to $m = -1$ behind the film, we see that there is a virtual image located there, with light coming from it in exactly the same way that light came from the actual object.
when the film was exposed. This image is what one sees when looking through the holographic film. Holograms are finding a number of applications. You may have a hologram on your credit card. This special type of hologram is called a rainbow hologram and is designed to be viewed in reflected white light.

### 38.5 Diffraction of X-Rays by Crystals

In principle, the wavelength of any electromagnetic wave can be determined if a grating of the proper spacing (on the order of $\lambda$) is available. X-rays, discovered by Wilhelm Roentgen (1845–1923) in 1895, are electromagnetic waves of very short wavelength (on the order of 0.1 nm). It would be impossible to construct a grating having such a small spacing by the cutting process described at the beginning of Section 38.4. The atomic spacing in a solid is known to be about 0.1 nm, however. In 1913, Max von Laue (1879–1960) suggested that the regular array of atoms in a crystal could act as a three-dimensional diffraction grating for x-rays. Subsequent experiments confirmed this prediction. The diffraction patterns from crystals are complex because of the three-dimensional nature of the crystal structure. Nevertheless, x-ray diffraction has proved to be an invaluable technique for elucidating these structures and for understanding the structure of matter.

Figure 38.20 shows one experimental arrangement for observing x-ray diffraction from a crystal. A collimated beam of monochromatic x-rays is incident on a crystal. The diffracted beams are very intense in certain directions, corresponding to constructive interference from waves reflected from layers of atoms in the crystal. The diffracted beams, which can be detected by a photographic film, form an array of spots known as a Laue pattern as in Figure 38.21a. One can deduce the crystalline structure by analyzing the positions and intensities of the various spots in the pattern. Figure 38.21b shows a Laue pattern from a crystalline enzyme, using a wide range of wavelengths so that a swirling pattern results.
The arrangement of atoms in a crystal of sodium chloride (NaCl) is shown in Figure 38.22. Each unit cell (the geometric solid that repeats throughout the crystal) is a cube having an edge length $a$. A careful examination of the NaCl structure shows that the ions lie in discrete planes (the shaded areas in Fig. 38.22). Now suppose an incident x-ray beam makes an angle $\theta$ with one of the planes as in Figure 38.23. The beam can be reflected from both the upper plane and the lower one, but the beam reflected from the lower plane travels farther than the beam reflected from the upper plane. The effective path difference is $2d \sin \theta$. The two beams reinforce each other (constructive interference) when this path difference equals some integer multiple of $\lambda$. The same is true for reflection from the entire family of parallel planes. Hence, the condition for constructive interference (maxima in the reflected beam) is

$$2d \sin \theta = m\lambda \quad m = 1, 2, 3, \ldots$$

(38.8)

This condition is known as Bragg’s law, after W. L. Bragg (1890–1971), who first derived the relationship. If the wavelength and diffraction angle are measured, Equation 38.8 can be used to calculate the spacing between atomic planes.

### 38.6 Polarization of Light Waves

In Chapter 34, we described the transverse nature of light and all other electromagnetic waves. Polarization, discussed in this section, is firm evidence of this transverse nature.

An ordinary beam of light consists of a large number of waves emitted by the atoms of the light source. Each atom produces a wave having some particular orientation of the electric field vector $\mathbf{E}$, corresponding to the direction of atomic vibration. The direction of polarization of each individual wave is defined to be the direction in which the electric field is vibrating. In Figure 38.24, this direction happens to lie along the $y$ axis. All individual electromagnetic waves traveling in the $x$ direction have an $\mathbf{E}$ vector parallel to the $yz$ plane, but this vector could be at any possible angle with respect to the $y$ axis. Because all directions of vibration from a wave source are possible, the resultant electromagnetic wave is a superposition of waves vibrating in many different directions. The result is an unpolarized light beam, represented in Figure 38.25a (page 1176). The direction of wave propagation in this figure is perpendicular to the page. The arrows show a few possible

**Figure 38.22** Crystalline structure of sodium chloride (NaCl). The length of the cube edge is $a = 0.562 \, 737$ nm.

**Figure 38.23** A two-dimensional description of the reflection of an x-ray beam from two parallel crystalline planes separated by a distance $d$. The beam reflected from the lower plane travels farther than the beam reflected from the upper plane by a distance $2d \sin \theta$.

**Figure 38.24** Schematic diagram of an electromagnetic wave propagating at velocity $\mathbf{c}$ in the $x$-direction. The electric field vibrates in the $xy$ plane, and the magnetic field vibrates in the $xz$ plane.
directions of the electric field vectors for the individual waves making up the resultant beam. At any given point and at some instant of time, all these individual electric field vectors add to give one resultant electric field vector.

As noted in Section 34.3, a wave is said to be linearly polarized if the resultant electric field \( \mathbf{E} \) vibrates in the same direction at all times at a particular point as shown in Figure 38.25b. (Sometimes, such a wave is described as plane-polarized, or simply polarized.) The plane formed by \( \mathbf{E} \) and the direction of propagation is called the plane of polarization of the wave. If the wave in Figure 38.24 represents the resultant of all individual waves, the plane of polarization is the \( xy \) plane.

A linearly polarized beam can be obtained from an unpolarized beam by removing all waves from the beam except those whose electric field vectors oscillate in a single plane. We now discuss four processes for producing polarized light from unpolarized light.

**Polarization by Selective Absorption**

The most common technique for producing polarized light is to use a material that transmits waves whose electric fields vibrate in a plane parallel to a certain direction and that absorbs waves whose electric fields vibrate in all other directions.

In 1938, E. H. Land (1909–1991) discovered a material, which he called Polaroid, that polarizes light through selective absorption. This material is fabricated in thin sheets of long-chain hydrocarbons. The sheets are stretched during manufacture so that the long-chain molecules align. After a sheet is dipped into a solution containing iodine, the molecules become good electrical conductors. Conduction takes place primarily along the hydrocarbon chains because electrons can move easily only along the chains. If light whose electric field vector is parallel to the chains is incident on the material, the electric field accelerates electrons along the chains and energy is absorbed from the radiation. Therefore, the light does not pass through the material. Light whose electric field vector is perpendicular to the chains passes through the material because electrons cannot move from one molecule to the next. As a result, when unpolarized light is incident on the material, the exiting light is polarized perpendicular to the molecular chains.

It is common to refer to the direction perpendicular to the molecular chains as the transmission axis. In an ideal polarizer, all light with \( \mathbf{E} \) parallel to the transmission axis is transmitted and all light with \( \mathbf{E} \) perpendicular to the transmission axis is absorbed.

Figure 38.26 represents an unpolarized light beam incident on a first polarizing sheet, called the polarizer. Because the transmission axis is oriented vertically in the figure, the light transmitted through this sheet is polarized vertically. A second polarizing sheet, called the analyzer, intercepts the beam. In Figure 38.26, the analyzer transmission axis is set at an angle \( \theta \) to the polarizer axis. We call the electric field vector of the first transmitted beam \( \mathbf{E}_0 \). The component of \( \mathbf{E}_0 \) perpendicular to the analyzer axis is completely absorbed. The component of \( \mathbf{E}_0 \) parallel to the
analyzer axis, which is transmitted through the analyzer, is \( E_0 \cos \theta \). Because the intensity of the transmitted beam varies as the square of its magnitude, we conclude that the intensity \( I \) of the (polarized) beam transmitted through the analyzer varies as

\[
I = I_{\text{max}} \cos^2 \theta
\]

(38.9)

where \( I_{\text{max}} \) is the intensity of the polarized beam incident on the analyzer. This expression, known as Malus’s law,\(^2\) applies to any two polarizing materials whose transmission axes are at an angle \( \theta \) to each other. This expression shows that the intensity of the transmitted beam is maximum when the transmission axes are parallel (\( \theta = 0 \) or \( 180^\circ \)) and is zero (complete absorption by the analyzer) when the transmission axes are perpendicular to each other. This variation in transmitted intensity through a pair of polarizing sheets is illustrated in Figure 38.27. Because the average value of \( \cos^2 \theta \) is \( \frac{1}{2} \), the intensity of initially unpolarized light is reduced by a factor of one-half as the light passes through a single ideal polarizer.

### Polarization by Reflection

When an unpolarized light beam is reflected from a surface, the polarization of the reflected light depends on the angle of incidence. If the angle of incidence is 0\(^\circ\), the reflected beam is unpolarized. For other angles of incidence, the reflected light is polarized to some extent, and for one particular angle of incidence, the reflected light is completely polarized. Let’s now investigate reflection at that special angle.

Suppose an unpolarized light beam is incident on a surface as in Figure 38.28a (page 1178). Each individual electric field vector can be resolved into two components: one parallel to the surface (and perpendicular to the page in Fig. 38.28, represented by the dots) and the other (represented by the orange arrows) perpendicular both to the first component and to the direction of propagation. Therefore, the polarization of the entire beam can be described by two electric field components in these directions. It is found that the parallel component represented by the dots reflects more strongly than the other component represented by the arrows, resulting in a partially polarized reflected beam. Furthermore, the refracted beam is also partially polarized.

Now suppose the angle of incidence \( \theta_1 \) is varied until the angle between the reflected and refracted beams is 90\(^\circ\) as in Figure 38.28b. At this particular angle of incidence, the reflected beam is completely polarized (with its electric field vector parallel to the surface) and the refracted beam is still only partially polarized. The angle of incidence at which this polarization occurs is called the polarizing angle \( \theta_p \).

\(^2\)Named after its discoverer, E. L. Malus (1775–1812). Malus discovered that reflected light was polarized by viewing it through a calcite (CaCO\(_3\)) crystal.
We can obtain an expression relating the polarizing angle to the index of refraction of the reflecting substance by using Figure 38.28b. From this figure, we see that $u_2 > 90^\circ$, therefore, $u_2 = 90^\circ - u_p$. Using Snell’s law of refraction (Eq. 35.8) gives

$$\frac{n_2}{n_1} = \frac{\sin u_1}{\sin u_2} = \frac{\sin u_p}{\sin u_2}$$

Because $\sin u_2 = \sin (90^\circ - u_p) = \cos u_p$, we can write this expression as $n_2/n_1 = \sin u_p/\cos u_p$, which means that

$$\tan u_p = \frac{n_2}{n_1} \tag{38.10}$$

This expression is called Brewster’s law, and the polarizing angle $u_p$ is sometimes called Brewster’s angle, after its discoverer, David Brewster (1781–1868). Because $n$ varies with wavelength for a given substance, Brewster’s angle is also a function of wavelength.

We can understand polarization by reflection by imagining that the electric field in the incident light sets electrons at the surface of the material in Figure 38.28b into oscillation. The component directions of oscillation are (1) parallel to the arrows shown on the refracted beam of light and therefore parallel to the reflected beam and (2) perpendicular to the page. The oscillating electrons act as dipole antennas radiating light with a polarization parallel to the direction of oscillation. Consult Figure 34.12, which shows the pattern of radiation from a dipole antenna. Notice that there is no radiation at an angle of $\theta = 0$, that is, along the oscillation direction of the antenna. Therefore, for the oscillations in direction 1, there is no radiation in the direction along the reflected ray. For oscillations in direction 2, the electrons radiate light with a polarization perpendicular to the page. Therefore, the light reflected from the surface at this angle is completely polarized parallel to the surface.

Polarization by reflection is a common phenomenon. Sunlight reflected from water, glass, and snow is partially polarized. If the surface is horizontal, the electric field vector of the reflected light has a strong horizontal component. Sunglasses made of polarizing material reduce the glare of reflected light. The transmission axes of such lenses are oriented vertically so that they absorb the strong horizontal component of the reflected light. If you rotate sunglasses through $90^\circ$, they are not as effective at blocking the glare from shiny horizontal surfaces.
38.6 Polarization of Light Waves

Polarization by Double Refraction

Solids can be classified on the basis of internal structure. Those in which the atoms are arranged in a specific order are called crystalline; the NaCl structure of Figure 38.22 is one example of a crystalline solid. Those solids in which the atoms are distributed randomly are called amorphous. When light travels through an amorphous material such as glass, it travels with a speed that is the same in all directions. That is, glass has a single index of refraction. In certain crystalline materials such as calcite and quartz, however, the speed of light is not the same in all directions. In these materials, the speed of light depends on the direction of propagation and on the plane of polarization of the light. Such materials are characterized by two indices of refraction. Hence, they are often referred to as double-refracting or birefringent materials.

When unpolarized light enters a birefringent material, it may split into an ordinary (O) ray and an extraordinary (E) ray. These two rays have mutually perpendicular polarizations and travel at different speeds through the material. The two speeds correspond to two indices of refraction, \( n_O \) for the ordinary ray and \( n_E \) for the extraordinary ray.

There is one direction, called the optic axis, along which the ordinary and extraordinary rays have the same speed. If light enters a birefringent material at an angle to the optic axis, however, the different indices of refraction will cause the two polarized rays to split and travel in different directions as shown in Figure 38.29.

The index of refraction \( n_O \) for the ordinary ray is the same in all directions. If one could place a point source of light inside the crystal as in Figure 38.30, the ordinary waves would spread out from the source as spheres. The index of refraction \( n_E \) varies with the direction of propagation. A point source sends out an extraordinary wave having wave fronts that are elliptical in cross section. The difference in speed for the two rays is a maximum in the direction perpendicular to the optic axis. For example, in calcite, \( n_O = 1.658 \) at a wavelength of 589.3 nm and \( n_E \) varies from 1.658 along the optic axis to 1.486 perpendicular to the optic axis. Values for \( n_O \) and the extreme value of \( n_E \) for various double-refracting crystals are given in Table 38.1.

If you place a calcite crystal on a sheet of paper and then look through the crystal at any writing on the paper, you would see two images as shown in Figure 38.31. As can be seen from Figure 38.29, these two images correspond to one formed by the ordinary ray and one formed by the extraordinary ray. If the two images are viewed through a sheet of rotating polarizing glass, they alternately appear and disappear because the ordinary and extraordinary rays are plane-polarized along mutually perpendicular directions.

Some materials such as glass and plastic become birefringent when stressed. Suppose an unstressed piece of plastic is placed between a polarizer and an analyzer so that light passes from polarizer to plastic to analyzer. When the plastic is unstressed and the analyzer axis is perpendicular to the polarizer axis, none of the polarized light passes through the analyzer. In other words, the unstressed plastic has no effect on the light passing through it. If the plastic is stressed, however, regions of greatest stress become birefringent and the polarization of the light passing through the plastic changes. Hence, a series of bright and dark bands is observed in the transmitted light, with the bright bands corresponding to regions of greatest stress.

Engineers often use this technique, called optical stress analysis, in designing structures ranging from bridges to small tools. They build a plastic model and analyze it under different load conditions to determine regions of potential weakness and failure under stress. An example of a plastic model under stress is shown in Figure 38.32.

**Polarization by Scattering**

When light is incident on any material, the electrons in the material can absorb and reradiate part of the light. Such absorption and reradiation of light by electrons in the gas molecules that make up air is what causes sunlight reaching an observer on the Earth to be partially polarized. You can observe this effect—called scattering—by looking directly up at the sky through a pair of sunglasses whose lenses are made of polarizing material. Less light passes through at certain orientations of the lenses than at others.

Figure 38.33 illustrates how sunlight becomes polarized when it is scattered. The phenomenon is similar to that creating completely polarized light upon reflection from a surface at Brewster’s angle. An unpolarized beam of sunlight traveling in the horizontal direction (parallel to the ground) strikes a molecule of one of the gases that make up air, setting the electrons of the molecule into vibration. These vibrating charges act like the vibrating charges in an antenna. The horizontal component of the electric field vector in the incident wave results in a horizontal component of the vibration of the charges, and the vertical component of the vector results in a vertical component of vibration. If the observer in Figure 38.33 is looking straight up (perpendicular to the original direction of propagation of the light), the vertical oscillations of the charges send no radiation toward the observer. Therefore, the observer sees light that is completely polarized in the horizontal direction as indicated by the orange arrows. If the observer looks in other directions, the light is partially polarized in the horizontal direction.

Variations in the color of scattered light in the atmosphere can be understood as follows. When light of various wavelengths $\lambda$ is incident on gas molecules of diameter $d$, where $d \ll \lambda$, the relative intensity of the scattered light varies as $1/\lambda^4$. The condition $d \ll \lambda$ is satisfied for scattering from oxygen (O$_2$) and nitrogen (N$_2$) molecules in the atmosphere, whose diameters are about 0.2 nm. Hence, short wavelengths (violet light) are scattered more efficiently than long wavelengths (red light). Therefore, when sunlight is scattered by gas molecules in the air, the short-wavelength radiation (violet) is scattered more intensely than the long-wavelength radiation (red).

When you look up into the sky in a direction that is not toward the Sun, you see the scattered light, which is predominantly violet. Your eyes, however, are not very sensitive to violet light. Light of the next color in the spectrum, blue, is scattered with less intensity than violet, but your eyes are far more sensitive to blue light than to violet light. Hence, you see a blue sky. If you look toward the west at sunset (or toward the east at sunrise), you are looking in a direction toward the Sun and are seeing light that has passed through a large distance of air. Most of the blue light has been scattered by the air between you and the Sun. The light that survives this
trip through the air to you has had much of its blue component scattered and is therefore heavily weighted toward the red end of the spectrum; as a result, you see the red and orange colors of sunset (or sunrise).

**Optical Activity**

Many important applications of polarized light involve materials that display optical activity. A material is said to be optically active if it rotates the plane of polarization of any light transmitted through the material. The angle through which the light is rotated by a specific material depends on the length of the path through the material and on concentration if the material is in solution. One optically active material is a solution of the common sugar dextrose. A standard method for determining the concentration of sugar solutions is to measure the rotation produced by a fixed length of the solution.

Molecular asymmetry determines whether a material is optically active. For example, some proteins are optically active because of their spiral shape.

The liquid crystal displays found in most calculators have their optical activity changed by the application of electric potential across different parts of the display. Try using a pair of polarizing sunglasses to investigate the polarization used in the display of your calculator.

**Quick Quiz 38.6** A polarizer for microwaves can be made as a grid of parallel metal wires approximately 1 cm apart. Is the electric field vector for microwaves transmitted through this polarizer (a) parallel or (b) perpendicular to the metal wires?

**Quick Quiz 38.7** You are walking down a long hallway that has many light fixtures in the ceiling and a very shiny, newly waxed floor. When looking at the floor, you see reflections of every light fixture. Now you put on sunglasses that are polarized. Some of the reflections of the light fixtures can no longer be seen. (Try it!) Are the reflections that disappear those (a) nearest to you, (b) farthest from you, or (c) at an intermediate distance from you?

**Summary**

- **Diffraction** is the deviation of light from a straight-line path when the light passes through an aperture or around an obstacle. Diffraction is due to the wave nature of light.

- **Rayleigh's criterion**, which is a limiting condition of resolution, states that two images formed by an aperture are just distinguishable if the central maximum of the diffraction pattern for one image falls on the first minimum of the diffraction pattern for the other image. The limiting angle of resolution for a slit of width \( a \) is \( \theta_{\text{min}} = \lambda / a \), and the limiting angle of resolution for a circular aperture of diameter \( D \) is given by \( \theta_{\text{min}} = 1.22\lambda / D \).

- The **Fraunhofer diffraction pattern** produced by a single slit of width \( a \) on a distant screen consists of a central bright fringe and alternating bright and dark fringes of much lower intensities. The angles \( \theta_{\text{dark}} \) at which the diffraction pattern has zero intensity, corresponding to destructive interference, are given by

\[
\sin \theta_{\text{dark}} = \frac{m\lambda}{a} \quad m = \pm 1, \pm 2, \pm 3, \ldots \tag{38.1}
\]

- A **diffraction grating** consists of a large number of equally spaced, identical slits. The condition for intensity maxima in the interference pattern of a diffraction grating for normal incidence is

\[
d \sin \theta_{\text{bright}} = m\lambda \quad m = 0, \pm 1, \pm 2, \pm 3, \ldots \tag{38.7}
\]

where \( d \) is the spacing between adjacent slits and \( m \) is the order number of the intensity maximum.

---

*continued*
When polarized light of intensity $I_{\text{max}}$ is emitted by a polarizer and then is incident on an analyzer, the light transmitted through the analyzer has an intensity equal to $I_{\text{max}} \cos^2 \theta$, where $\theta$ is the angle between the polarizer and analyzer transmission axes.

In general, reflected light is partially polarized. Reflected light, however, is completely polarized when the angle of incidence is such that the angle between the reflected and refracted beams is 90°. This angle of incidence, called the polarizing angle $\theta_p$, satisfies Brewster’s law:

$$\tan \theta_p = \frac{n_2}{n_1}$$

where $n_1$ is the index of refraction of the medium in which the light initially travels and $n_2$ is the index of refraction of the reflecting medium.

**Objective Questions**

1. Certain sunglasses use a polarizing material to reduce the intensity of light reflected as glare from water or automobile windshields. What orientation should the polarizing filters have to be most effective? (a) The polarizers should absorb light with its electric field horizontal. (b) The polarizers should absorb light with its electric field vertical. (c) The polarizers should absorb both horizontal and vertical electric fields. (d) The polarizers should not absorb either horizontal or vertical electric fields.

2. What is most likely to happen to a beam of light when it reflects from a shiny metallic surface at an arbitrary angle? Choose the best answer. (a) It is totally absorbed by the surface. (b) It is totally polarized. (c) It is unpolarized. (d) It is partially polarized. (e) More information is required.

3. In Figure 38.4, assume the slit is in a barrier that is opaque to x-rays as well as to visible light. The photograph in Figure 38.4b shows the diffraction pattern produced with visible light. What will happen if the experiment is repeated with x-rays as the incoming wave and with no other changes? (a) The diffraction pattern is similar. (b) There is no noticeable diffraction pattern but rather a projected shadow of high intensity on the screen, having the same width as the slit. (c) The central maximum is much wider, and the minima occur at larger angles than with visible light. (d) No x-rays reach the screen.

4. A Fraunhofer diffraction pattern is produced on a screen located 1.00 m from a single slit. If a light source of wavelength $5.00 \times 10^{-7}$ m is used and the distance from the center of the central bright fringe to the first dark fringe is $5.00 \times 10^{-3}$ m, what is the slit width? (a) 0.010 mm (b) 0.100 mm (c) 0.200 mm (d) 1.00 mm (e) 0.005 00 mm

5. Consider a wave passing through a single slit. What happens to the width of the central maximum of its diffraction pattern as the slit is made half as wide? (a) It becomes one-fourth as wide. (b) It becomes one-half as wide. (c) Its width does not change. (d) It becomes twice as wide. (e) It becomes four times as wide.

6. Assume Figure 38.1 was photographed with red light of a single wavelength $\lambda_0$. The light passed through a single slit of width $a$ and traveled distance $L$ to the screen where the photograph was made. Consider the width of the central bright fringe, measured between the centers of the dark fringes on both sides of it. Rank from largest to smallest the widths of the central fringe in the following situations and note any cases of equality. (a) The experiment is performed as photographed. (b) The experiment is performed with light whose frequency is increased by 50%. (c) The experiment is performed with light whose wavelength is increased by 50%. (d) The experiment is performed with the original light and with a slit of width 2$a$. (e) The experiment is performed with the original light and slit and with distance 2$L$ to the screen.

7. If plane polarized light is sent through two polarizers, the first at 45° to the original plane of polarization and the second at 90° to the original plane of polarization, what fraction of the original polarized intensity passes through the last polarizer? (a) 0 (b) $\frac{1}{4}$ (c) $\frac{1}{2}$ (d) $\frac{1}{6}$ (e) $\frac{1}{8}$

8. Why is it advantageous to use a large-diameter objective lens in a telescope? (a) It diffracts the light more effectively than smaller-diameter objective lenses. (b) It increases its magnification. (c) It enables you to see more objects in the field of view. (d) It reflects unwanted wavelengths. (e) It increases its resolution.

9. What combination of optical phenomena causes the bright colored patterns sometimes seen on wet streets covered with a layer of oil? Choose the best answer. (a) diffraction and polariztion (b) interference and diffraction (c) polarization and reflection (d) refraction and diffraction (e) refraction and interference

10. When you receive a chest x-ray at a hospital, the x-rays pass through a set of parallel ribs in your chest. Do your ribs act as a diffraction grating for x-rays? (a) Yes. They produce diffracted beams that can be observed separately. (b) Not to a measurable extent. The ribs are too far apart. (c) Essentially not. The ribs are too close together. (d) Essentially not. The ribs are too few in number. (e) Absolutely not. X-rays cannot diffract.

11. When unpolarized light passes through a diffraction grating, does it become polarized? (a) No, it does not. (b) Yes, it does, with the transmission axis parallel to the slits or grooves in the grating. (c) Yes, it does, with the transmission axis perpendicular to the slits or grooves in the grating. (d) It possibly does because an electric field above some threshold is blocked out by the grating if the field is perpendicular to the slits.
12. Off in the distance, you see the headlights of a car, but they are indistinguishable from the single headlight of a motorcycle. Assume the car’s headlights are now switched from low beam to high beam so that the light intensity you receive becomes three times greater. What then happens to your ability to resolve the two light sources? (a) It increases by a factor of 9. (b) It increases by a factor of 3. (c) It remains the same. (d) It becomes one-third as good. (e) It becomes one-ninth as good.

Conceptual Questions

1. The atoms in a crystal lie in planes separated by a few tenths of a nanometer. Can they produce a diffraction pattern for visible light as they do for x-rays? Explain your answer with reference to Bragg’s law.

2. Holding your hand at arm’s length, you can readily block sunlight from reaching your eyes. Why can you not block sound from reaching your ears this way?

3. How could the index of refraction of a flat piece of opaque obsidian glass be determined?

4. (a) Is light from the sky polarized? (b) Why is it that clouds seen through Polaroid glasses stand out in bold contrast to the sky?

5. A laser beam is incident at a shallow angle on a horizontal machinist’s ruler that has a finely calibrated scale. The engraved rulings on the scale give rise to a diffraction pattern on a vertical screen. Discuss how you can use this technique to obtain a measure of the wavelength of the laser light.

6. If a coin is glued to a glass sheet and this arrangement is held in front of a laser beam, the projected shadow has diffraction rings around its edge and a bright spot in the center. How are these effects possible?

7. Fingerprints left on a piece of glass such as a window-pane often show colored spectra like that from a diffraction grating. Why?

8. A laser produces a beam a few millimeters wide, with uniform intensity across its width. A hair is stretched vertically across the front of the laser to cross the beam. (a) How is the diffraction pattern it produces on a distant screen related to that of a vertical slit equal in width to the hair? (b) How could you determine the width of the hair from measurements of its diffraction pattern?

9. A radio station serves listeners in a city to the northeast of its broadcast site. It broadcasts from three adjacent towers on a mountain ridge, along a line running east to west, in what’s called a phased array. Show that by introducing time delays among the signals the individual towers radiate, the station can maximize net intensity in the direction toward the city (and in the opposite direction) and minimize the signal transmitted in other directions.

10. John William Strutt, Lord Rayleigh (1842–1919), invented an improved foghorn. To warn ships of a coastline, a foghorn should radiate sound in a wide horizontal sheet over the ocean’s surface. It should not waste energy by broadcasting sound upward or downward. Rayleigh’s foghorn trumpet is shown in two possible configurations, horizontal and vertical, in Figure CQ38.10. Which is the correct orientation? Decide whether the long dimension of the rectangular opening should be horizontal or vertical and argue for your decision.

Problems

The problems found in this chapter may be assigned online in Enhanced WebAssign.

1. straightforward; 2. intermediate; 3. challenging

1. full solution available in the Student Solutions Manual/Study Guide

Analysis Model tutorial available in Enhanced WebAssign

Guided Problem

Master It tutorial available in Enhanced WebAssign

Watch It video solution available in Enhanced WebAssign
Section 38.2 Diffraction Patterns from Narrow Slits

1. Light of wavelength 587.5 nm illuminates a slit of width 0.75 mm. (a) At what distance from the slit should a screen be placed if the first minimum in the diffraction pattern is to be 0.85 mm from the central maximum? (b) Calculate the width of the central maximum.

2. Helium–neon laser light (\(\lambda = 632.8\) nm) is sent through a 0.300-mm-wide single slit. What is the width of the central maximum on a screen 1.00 m from the slit?

3. Sound with a frequency 650 Hz from a distant source passes through a doorway 1.10 m wide in a sound-absorbing wall. Find (a) the number and (b) the angular directions of the diffraction minima at listening positions along a line parallel to the wall.

4. A horizontal laser beam of wavelength 632.8 nm has a circular cross section 2.00 mm in diameter. A rectangular aperture is to be placed in the center of the beam so that when the light falls perpendicularly on a wall 4.50 m away, the central maximum fills a rectangle 110 mm wide and 6.00 mm high. The dimensions are measured between the minima bracketing the central maximum. Find the required (a) width and (b) height of the aperture. (c) Is the longer dimension of the central bright patch in the diffraction pattern horizontal or vertical? (d) Is the longer dimension of the aperture horizontal or vertical? (e) Explain the relationship between these two rectangles, using a diagram.

5. Coherent microwaves of wavelength 5.00 cm enter a tall, narrow window in a building otherwise essentially opaque to the microwaves. If the window is 36.0 cm wide, what is the distance from the central maximum to the first-order minimum along a wall 6.50 m from the window?

6. Light of wavelength 540 nm passes through a slit of width 0.200 mm. (a) The width of the central maximum on a screen is 8.10 mm. How far is the screen from the slit? (b) Determine the width of the first bright fringe to the side of the central maximum.

7. A screen is placed 50.0 cm from a single slit, which is illuminated with light of wavelength 690 nm. If the distance between the first and third minima in the diffraction pattern is 3.00 mm, what is the width of the slit?

8. A screen is placed a distance \(L\) from a single slit of width \(a\), which is illuminated with light of wavelength \(\lambda\). Assume \(L >> a\). If the distance between the minima for \(m = m_1\) and \(m = m_2\) in the diffraction pattern is \(\Delta y\), what is the width of the slit?

9. Assume light of wavelength 650 nm passes through two slits 3.00 \(\mu\)m wide, with their centers 9.00 \(\mu\)m apart. Make a sketch of the combined diffraction and interference pattern in the form of a graph of intensity versus \(\phi = (\pi a \sin \theta)/\lambda\). You may use Figure 38.7 as a starting point.

10. What If? Suppose light strikes a single slit of width \(a\) at an angle \(\beta\) from the perpendicular direction as shown in Figure P38.10. Show that Equation 38.1, the condition for destructive interference, must be modified to read

\[
\sin \theta_{\text{dark}} = \frac{m \lambda}{a} - \sin \beta
\]

\(m = \pm 1, \pm 2, \pm 3, \ldots\)

A diffraction pattern is formed on a screen 120 cm away from a 0.400-mm-wide slit. Monochromatic 546.1-nm light is used. Calculate the fractional intensity \(I/I_{\text{max}}\) at a point on the screen 4.10 mm from the center of the principal maximum.

11. Coherent light of wavelength 501.5 nm is sent through two parallel slits in an opaque material. Each slit is 0.700 \(\mu\)m wide. Their centers are 2.80 \(\mu\)m apart. The light then falls on a semicylindrical screen, with its axis at the midline between the slits. We would like to describe the appearance of the pattern of light visible on the screen. (a) Find the direction for each two-slit interference maximum on the screen as an angle away from the bisector of the line joining the slits. (b) How many angles are there that represent two-slit interference maxima? (c) Find the direction for each single-slit interference minimum on the screen as an angle away from the bisector of the line joining the slits. (d) How many angles are there that represent single-slit interference minima? (e) How many of the angles in part (d) are identical to those in part (a)? (f) How many bright fringes are visible on the screen? (g) If the intensity of the central fringe is \(I_{\text{max}}\), what is the intensity of the last fringe visible on the screen?

12. A beam of monochromatic light is incident on a single slit of width 0.600 mm. A diffraction pattern forms on a wall 1.30 m beyond the slit. The distance between the positions of zero intensity on both sides of the central maximum is 2.00 mm. Calculate the wavelength of the light.

Section 38.3 Resolution of Single-Slit and Circular Apertures

Note: In Problems 14, 19, 22, 23, and 67, you may use the Rayleigh criterion for the limiting angle of resolution of an eye. The standard may be overly optimistic for human vision.

14. The pupil of a cat’s eye narrows to a vertical slit of width 0.500 mm in daylight. Assume the average wavelength of the light is 500 nm. What is the angular resolution for horizontally separated mice?

15. The angular resolution of a radio telescope is to be 0.100° when the incident waves have a wavelength of 3.00 mm. What minimum diameter is required for the telescope’s receiving dish?

16. A pinhole camera has a small circular aperture of diameter \(D\). Light from distant objects passes through the aperture into an otherwise dark box, falling on a screen at the other end of the box. The aperture in a pinhole camera has diameter \(D = 0.600\) mm. Two
point sources of light of wavelength 550 nm are at a distance \( L \) from the hole. The separation between the sources is 2.80 cm, and they are just resolved by the camera. What is \( L \)?

17. The objective lens of a certain refracting telescope has a diameter of 58.0 cm. The telescope is mounted in a satellite that orbits the Earth at an altitude of 270 km to view objects on the Earth’s surface. Assuming an average wavelength of 500 nm, find the minimum distance between two objects on the ground if their images are to be resolved by this lens.

18. Yellow light of wavelength 589 nm is used to view an object under a microscope. The objective lens diameter is 9.00 mm. (a) What is the limiting angle of resolution? (b) Suppose it is possible to use visible light of any wavelength. What color should you choose to give the smallest possible angle of resolution, and what is this angle? (c) Suppose water fills the space between the object and the objective. What effect does this change have on the resolving power when 589-nm light is used?

19. What is the approximate size of the smallest object on the Earth that astronauts can resolve by eye when they are orbiting 250 km above the Earth? Assume \( \lambda = 500 \text{ nm} \) and a pupil diameter of 5.00 mm.

20. A helium–neon laser emits light that has a wavelength of 632.8 nm. The circular aperture through which the beam emerges has a diameter of 0.500 cm. Estimate the diameter of the beam 10.0 km from the laser.

21. To increase the resolving power of a microscope, the object and the objective are immersed in oil (\( n = 1.5 \)). If the limiting angle of resolution without the oil is 0.60 \( \mu \)rad, what is the limiting angle of resolution with the oil? \( \text{Hint:} \) The oil changes the wavelength of the light.

22. Narrow, parallel, glowing gas-filled tubes in a variety of colors form block letters to spell out the name of a nightclub. Adjacent tubes are all 2.80 cm apart. The tubes forming one letter are filled with neon and radiate predominantly red light with a wavelength of 640 nm. For another letter, the tubes emit predominantly blue light at 440 nm. The pupil of a dark-adapted viewer’s eye is 5.20 mm in diameter. (a) Which color is easier to resolve? State how you decide. (b) If she is in a certain range of distances away, the viewer can resolve the separate tubes of one color but not the other. The viewer’s distance must be in what range for her to resolve the tubes of only one of these two colors?

23. Impressionist painter Georges Seurat created paintings with an enormous number of dots of pure pigment, each of which was approximately 2.00 mm in diameter. The idea was to have colors such as red and green next to each other to form a scintillating canvas, such as in his masterpiece, A Sunday Afternoon on the Island of La Grande Jatte (Fig. P38.25). Assume \( \lambda = 500 \text{ nm} \) and a pupil diameter of 5.00 mm. Beyond what distance would a viewer be unable to discern individual dots on the canvas?

24. A circular radar antenna on a Coast Guard ship has a diameter of 2.10 m and radiates at a frequency of 15.0 GHz. Two small boats are located 9.00 km away from the ship. How close together could the boats be and still be detected as two objects?

Section 38.4 The Diffraction Grating

Note: In the following problems, assume the light is incident normally on the gratings.

25. A helium–neon laser (\( \lambda = 632.8 \text{ nm} \)) is used to calibrate a diffraction grating. If the first-order maximum occurs at 20.5°, what is the spacing between adjacent grooves in the grating?

26. White light is spread out into its spectral components by a diffraction grating. If the grating has 2 000 grooves per centimeter, at what angle does red light of wavelength 640 nm appear in first order?

27. Consider an array of parallel wires with uniform spacing of 1.30 cm between centers. In air at 20.0°C, ultrasound with a frequency of 37.2 kHz from a distant source is incident perpendicular to the array. (a) Find the number of directions on the other side of the array in which there is a maximum of intensity. (b) Find the angle for each of these directions relative to the direction of the incident beam.

28. Three discrete spectral lines occur at angles of 10.1°, 13.7°, and 14.8° in the first-order spectrum of a grating spectrometer. (a) If the grating has 3 660 slits/cm, what are the wavelengths of the light? (b) At what angles are these lines found in the second-order spectrum?

29. The laser in a compact disc player must precisely follow the spiral track on the CD, along which the distance between one loop of the spiral and the next is only about 1.25 \( \mu \text{m} \). Figure P38.29 (page 1186) shows how a diffraction grating is used to provide information to keep the beam on track. The laser light passes through a diffraction grating before it reaches the CD. The strong central maximum of the diffraction pattern is used to read the information in the track of pits. The two first-order side maxima are designed to fall on the flat surfaces on both sides of the information track and are used for steering. As long as both beams are reflecting from smooth,
nonpitted surfaces, they are detected with constant high intensity. If the main beam wanders off the track, however, one of the side beams begins to strike pits on the information track and the reflected light diminishes. This change is used with an electronic circuit to guide the beam back to the desired location. Assume the laser light has a wavelength of 780 nm and the diffraction grating is positioned 6.90 μm from the disk. Assume the first-order beams are to fall on the CD 0.400 μm on either side of the information track. What should be the number of grooves per millimeter in the grating?

32. A diffraction grating has 4200 rulings/cm. On a screen 2.00 m from the grating, it is found that for a particular order \( m \), the maxima corresponding to two closely spaced wavelengths of sodium (589.0 nm and 589.6 nm) are separated by 1.54 mm. Determine the value of \( m \).

33. The hydrogen spectrum includes a red line at 656 nm and a blue-violet line at 434 nm. What are the angular separations between these two spectral lines for all visible orders obtained with a diffraction grating that has 4500 grooves/cm?

34. Show that whenever white light is passed through a diffraction grating of any spacing size, the violet end of the spectrum in the third order on a screen always overlaps the red end of the spectrum in the second order.

35. Light of wavelength 500 nm is incident normally on a diffraction grating. If the third-order maximum of the diffraction pattern is observed at 32.0°, (a) what is the number of rulings per centimeter for the grating? (b) Determine the total number of primary maxima that can be observed in this situation.

36. A wide beam of laser light with a wavelength of 632.8 nm is directed through several narrow parallel slits, separated by 1.20 mm, and falls on a sheet of photographic film 1.40 m away. The exposure time is chosen so that the film stays unexposed everywhere except at the central region of each bright fringe. (a) Find the distance between these interference maxima. The film is printed as a transparency; it is opaque everywhere except at the exposed lines. Next, the same beam of laser light is directed through the transparency and allowed to fall on a screen 1.40 m beyond. (b) Argue that several narrow, parallel, bright regions, separated by 1.20 mm, appear on the screen as real images of the original slits. (A similar train of thought, at a soccer game, led Dennis Gabor to invent holography.)

37. A beam of bright red light of wavelength 654 nm passes through a diffraction grating. Enclosing the space beyond the grating is a large semicylindrical screen centered on the grating, with its axis parallel to the slits in the grating. Fifteen bright spots appear on the screen. Find (a) the maximum and (b) the minimum possible values for the slit separation in the diffraction grating.

### Section 38.5 Diffraction of X-Rays by Crystals

38. If the spacing between planes of atoms in a NaCl crystal is 0.281 nm, what is the predicted angle at which 0.140-nm x-rays are diffracted in a first-order maximum?

39. Potassium iodide (KI) has the same crystalline structure as NaCl, with atomic planes separated by 0.353 nm. A monochromatic x-ray beam shows a first-order diffraction maximum when the grazing angle is 7.60°. Calculate the x-ray wavelength.

40. Monochromatic x-rays (\( \lambda = 0.166 \) nm) from a nickel target are incident on a potassium chloride (KCl) crystal surface. The spacing between planes of atoms in KCl is 0.314 nm. At what angle (relative to the surface) should the beam be directed for a second-order maximum to be observed?

41. The first-order diffraction maximum is observed at 12.6° for a crystal having a spacing between planes of atoms of 0.250 nm. (a) What wavelength x-ray is used to observe this first-order pattern? (b) How many orders can be observed for this crystal at this wavelength?

### Section 38.6 Polarization of Light Waves

Problem 62 in Chapter 34 can be assigned with this section.

42. Why is the following situation impossible? A technician is measuring the index of refraction of a solid material by observing the polarization of light reflected from its surface. She notices that when a light beam is projected from air onto the material surface, the reflected light is totally polarized parallel to the surface when the incident angle is 41.0°.

43. Plane-polarized light is incident on a single polarizing disk with the direction of \( \mathbf{E}_0 \) parallel to the direction of the transmission axis. Through what angle should the disk be rotated so that the intensity in the transmitted beam is reduced by a factor of (a) 3.00, (b) 5.00, and (c) 10.0?
44. The angle of incidence of a light beam onto a reflecting surface is continuously variable. The reflected ray in air is completely polarized when the angle of incidence is 48.0°. What is the index of refraction of the reflecting material?

45. Unpolarized light passes through two ideal Polaroid sheets. The axis of the first is vertical, and the axis of the second is at 30.0° to the vertical. What fraction of the incident light is transmitted?

46. Two handheld radio transceivers with dipole antennas are separated by a large fixed distance. If the transmitting antenna is vertical, what fraction of the maximum received power will appear in the receiving antenna when it is inclined from the vertical by (a) 15.0°, (b) 45.0°, and (c) 90.0°?

47. You use a sequence of ideal polarizing filters, each with its axis making the same angle with the axis of the previous filter, to rotate the plane of polarization of a polarized light beam by a total of 45.0°. You wish to have an intensity reduction no larger than 10.0%. (a) How many polarizers do you need to achieve your goal? (b) What is the angle between adjacent polarizers?

48. An unpolarized beam of light is incident on a stack of ideal polarizing filters. The axis of the first filter is perpendicular to the axis of the last filter in the stack. Find the fraction by which the transmitted beam's intensity is reduced in the three following cases. (a) Three filters are in the stack, each with its transmission axis at 45.0° relative to the preceding filter. (b) Four filters are in the stack, each with its transmission axis at 30.0° relative to the preceding filter. (c) Seven filters are in the stack, each with its transmission axis at 15.0° relative to the preceding filter. (d) Comment on comparing the answers to parts (a), (b), and (c).

49. The critical angle for total internal reflection for sapphire surrounded by air is 34.4°. Calculate the polarizing angle for sapphire.

50. For a particular transparent medium surrounded by air, find the polarizing angle $\theta_p$ in terms of the critical angle for total internal reflection $\theta_i$.

51. Three polarizing plates whose planes are parallel are centered on a common axis. The directions of the transmission axes relative to the common vertical direction are shown in Figure P38.51. A linearly polarized beam of light with plane of polarization parallel to the vertical reference direction is incident from the left onto the first disk with intensity $I_1 = 10.0$ units (arbitrary). Calculate the transmitted intensity $I_2$ when $\theta_1 = 20.0°$, $\theta_2 = 40.0°$, and $\theta_3 = 60.0°$. Hint: Make repeated use of Malus's law.

52. Two polarizing sheets are placed together with their transmission axes crossed so that no light is transmitted. A third sheet is inserted between them with its transmission axis at an angle of 45.0° with respect to each of the other axes. Find the fraction of incident unpolarized light intensity transmitted by the three-sheet combination. (Assume each polarizing sheet is ideal.)

Additional Problems

53. In a single-slit diffraction pattern, assuming each side maximum is halfway between the adjacent minima, find the ratio of the intensity of (a) the first-order side maximum and (b) the second-order side maximum to the intensity of the central maximum.

54. Laser light with a wavelength of 632.8 nm is directed through one slit or two slits and allowed to fall on a screen 2.60 m beyond. Figure P38.54 shows the pattern on the screen, with a centimeter ruler below it. (a) Did the light pass through one slit or two slits? Explain how you can determine the answer. (b) If one slit, find its width. If two slits, find the distance between their centers.

55. In water of uniform depth, a wide pier is supported on pilings in several parallel rows 2.80 m apart. Ocean waves of uniform wavelength roll in, moving in a direction that makes an angle of 80.0° with the rows of pilings. Find the three longest wavelengths of waves that are strongly reflected by the pilings.

56. The second-order dark fringe in a single-slit diffraction pattern is 1.40 mm from the center of the central maximum. Assuming the screen is 85.0 cm from a slit of width 0.800 mm and assuming monochromatic incident light, calculate the wavelength of the incident light.

57. Light from a helium–neon laser ($\lambda = 632.8$ nm) is incident on a single slit. What is the maximum width of the slit for which no diffraction minima are observed?

58. Two motorcycles separated laterally by 2.30 m are approaching an observer wearing night-vision goggles sensitive to infrared light of wavelength 885 nm. (a) Assume the light propagates through perfectly steady and uniform air. What aperture diameter is required if the motorcycles' headlights are to be resolved at a distance of 12.0 km? (b) Comment on how realistic the assumption in part (a) is.
59. The Very Large Array (VLA) is a set of 27 radio telescope dishes in Catron and Socorro counties, New Mexico (Fig. P38.59). The antennas can be moved apart on railroad tracks, and their combined signals give the resolving power of a synthetic aperture 36.0 km in diameter. (a) If the detectors are tuned to a frequency of 1.40 GHz, what is the angular resolution of the VLA? (b) Clouds of interstellar hydrogen radiate at the frequency used in part (a). What must be the separation distance of two clouds at the center of the galaxy, 26,000 light-years away, if they are to be resolved? (c) What If? As the telescope looks up, a circling hawk looks down. Assume the hawk is most sensitive to green light having a wavelength of 500 nm and has a pupil of diameter 12.0 mm. Find the angular resolution of the hawk’s eye. (d) A mouse is on the ground 30.0 m below. By what distance must the mouse’s whiskers be separated if the hawk can resolve them?

60. Two wavelengths \( \lambda \) and \( \lambda + \Delta \lambda \) (with \( \Delta \lambda \ll \lambda \)) are incident on a diffraction grating. Show that the angular separation between the spectral lines in the \( m \)th-order spectrum is

\[
\Delta \theta = \frac{\Delta \lambda}{\sqrt{(d/m)^2 - \lambda^2}}
\]

where \( d \) is the slit spacing and \( m \) is the order number.

61. Review. A beam of 541-nm light is incident on a diffraction grating that has 400 grooves/mm. (a) Determine the angle of the second-order ray. (b) What If? If the entire apparatus is immersed in water, what is the new second-order angle of diffraction? (c) Show that the two diffracted rays of parts (a) and (b) are related through the law of refraction.

62. Why is the following situation impossible? A technician is passing into the next lab station, startling a coworker.

63. A 750-nm light beam in air hits the flat surface of a certain liquid, and the beam is split into a reflected ray and a refracted ray. If the reflected ray is completely polarized when it is at 36.0° with respect to the surface, what is the wavelength of the refracted ray?

64. Iridescent peacock feathers are shown in Figure P38.64a. The surface of one microscopic barbule is composed of transparent keratin that supports rods of dark brown melanin in a regular lattice, represented in Figure P38.64b. (Your fingernails are made of keratin, and melanin is the dark pigment giving color to human skin.) In a portion of the feather that can appear turquoise (blue-green), assume the melanin rods are uniformly separated by 0.25 \( \mu \text{m} \), with air between them. (a) Explain how this structure can appear turquoise when it contains no blue or green pigment. (b) Explain how it can also appear violet if light falls on it in a different direction. (c) Explain how it can present different colors to your two eyes simultaneously, which is a characteristic of iridescence. (d) A compact disc can appear to be any color of the rainbow. Explain why the portion of the feather in Figure P38.64b cannot appear yellow or red. (e) What could be different about the array of melanin rods in a portion of the feather that does appear to be red?

65. Light in air strikes a water surface at the polarizing angle. The part of the beam refracted into the water strikes a submerged slab of material with refractive index \( n = 1.62 \) as shown in Figure P38.65. The light reflected from the upper surface of the slab is completely polarized. Find the angle \( \theta \) between the water surface and the surface of the slab.

66. Light in air (assume \( n = 1 \)) strikes the surface of a liquid of index of refraction \( n_l \) at the polarizing angle. The part of the beam refracted into the liquid strikes a submerged slab of material with refractive index \( n \) as shown in Figure P38.65. The light reflected from the upper surface of the slab is completely polarized. Find the angle \( \theta \) between the water surface and the surface of the slab as a function of \( n \) and \( n_l \).

67. An American standard analog television picture (non-HDTV), also known as NTSC, is composed of approximately 485 visible horizontal lines of varying light intensity. Assume your ability to resolve the lines is limited only by the Rayleigh criterion, the pupils of
your eyes are 5.00 mm in diameter, and the average wavelength of the light coming from the screen is 550 nm. Calculate the ratio of the minimum viewing distance to the vertical dimension of the picture such that you will not be able to resolve the lines.

68. A pinhole camera has a small circular aperture of diameter \( D \). Light from distant objects passes through the aperture into an otherwise dark box, falling on a screen located a distance \( L \) away. If \( D \) is too large, the display on the screen will be fuzzy because a bright point in the field of view will send light onto a circle of diameter slightly larger than \( D \). On the other hand, if \( D \) is too small, diffraction will blur the display on the screen. The screen shows a reasonably sharp image if the diameter of the central disk of the diffraction pattern, specified by Equation 38.6, is equal to \( D \) at the screen. (a) Show that for monochromatic light with plane wave fronts and \( L \gg D \), the condition for a sharp view is fulfilled if \( D^2 = 2.44AL \). (b) Find the optimum pinhole diameter for 500-nm light projected onto a screen 15.0 cm away.

69. The scale of a map is a number of kilometers per centimeter specifying the distance on the ground that any distance on the map represents. The scale of a spectrum is its dispersion, a number of nanometers per centimeter, specifying the change in wavelength that a distance across the spectrum represents. You must know the dispersion if you want to compare one spectrum with another or make a measurement of, for example, a Doppler shift. Let \( \gamma \) represent the position relative to the center of a diffraction pattern projected onto a flat screen at distance \( L \) by a diffraction grating with slit spacing \( d \). The dispersion is \( \Delta \lambda/\Delta y \). (a) Prove that the dispersion is given by

\[
\frac{\Delta \lambda}{\Delta y} = \frac{L^2d}{m(L^2 + \gamma^2)^{3/2}}
\]

(b) A light with a mean wavelength of 550 nm is analyzed with a grating having 8,000 rulings/cm projected onto a screen 2.40 m away. Calculate the dispersion in first order.

70. (a) Light traveling in a medium of index of refraction \( n_1 \) is incident at an angle \( \theta \) on the surface of a medium of index \( n_2 \). The angle between reflected and refracted rays is \( \beta \). Show that

\[
\tan \theta = \frac{n_2 \sin \beta}{n_1 - n_2 \cos \beta}
\]

(b) What If? Show that this expression for \( \tan \theta \) reduces to Brewster’s law when \( \beta = 90^\circ \).

71. The intensity of light in a diffraction pattern of a single slit is described by the equation

\[
I = I_{\text{max}} \frac{\sin^2 \phi}{\phi^2}
\]

where \( \phi = (\pi a \sin \theta)/\lambda \). The central maximum is at \( \phi = 0 \), and the side maxima are approximately at \( \phi = (m + \frac{1}{2})\pi \) for \( m = 1, 2, 3, \ldots \). Determine more precisely (a) the location of the first side maximum, where \( m = 1 \), and (b) the location of the second side maximum. Suggestion: Observe in Figure 38.6a that the graph of intensity versus \( \phi \) has a horizontal tangent at maxima and also at minima.

72. How much diffraction spreading does a light beam undergo? One quantitative answer is the full width at half maximum of the central maximum of the single-slit Fraunhofer diffraction pattern. You can evaluate this angle of spreading in this problem. (a) In Equation 38.2, define \( \phi = \pi a \sin \theta/\lambda \) and show that at the point where \( I = 0.5I_{\text{max}} \) we must have \( \phi = \sqrt{2} \sin \phi \). (b) Let \( \gamma_1 = \sin \phi \) and \( \gamma_2 = \phi/\sqrt{2} \). Plot \( \gamma_1 \) and \( \gamma_2 \) on the same set of axes over a range from \( \phi = 1 \) rad to \( \phi = \pi/2 \) rad. Determine \( \phi \) from the point of intersection of the two curves. (c) Then show that if the fraction \( \lambda/a \) is not large, the angular full width at half maximum of the central diffraction maximum is \( \theta = 0.885\lambda/a \). (d) What If? Another method to solve the transcendental equation \( \phi = \sqrt{2} \sin \phi \) in part (a) is to guess a first value of \( \phi \), use a computer or calculator to see how nearly it fits, and continue to update your estimate until the equation balances. How many steps (iterations) does this process take?

73. Two closely spaced wavelengths of light are incident on a diffraction grating. (a) Starting with Equation 38.7, show that the angular dispersion of the grating is given by

\[
\frac{d\theta}{d\lambda} = \frac{m}{d \cos \theta}
\]

(b) A square grating 2.00 cm on each side containing 8,000 equally spaced slits is used to analyze the spectrum of mercury. Two closely spaced lines emitted by this element have wavelengths of 579.065 nm and 576.959 nm. What is the angular separation of these two wavelengths in the second-order spectrum?

74. Light of wavelength 632.8 nm illuminates a single slit, and a diffraction pattern is formed on a screen 1.00 m from the slit. (a) Using the data in the following table, plot relative intensity versus position. Choose an appropriate value for the slit width \( a \) and, on the same graph used for the experimental data, plot the theoretical expression for the relative intensity

\[
\frac{I}{I_{\text{max}}} = \frac{\sin^2 \phi}{\phi^2}
\]

where \( \phi = (\pi a \sin \theta)/\lambda \). (b) What value of \( a \) gives the best fit of theory and experiment?

Challenge Problems

75. Figure P38.75a is a three-dimensional sketch of a birefringent crystal. The dotted lines illustrate how a thin, parallel-faced slab of material could be cut from the larger specimen with the crystal’s optic axis parallel to the faces of the plate. A section cut from the crystal in this manner is known as a retardation plate. When a beam of light is incident on the plate perpendicular to the direction of the optic axis as shown in Figure P38.75b, the O ray and the E ray travel along a single straight line, but with different speeds. The figure shows the wave fronts for the two rays. (a) Let the thickness of the plate be \( d \). Show that the phase difference between the O ray and the E ray after traveling the thickness of the plate is

\[
\theta = \frac{2\pi d}{\lambda} |n_O - n_E|
\]

where \( \lambda \) is the wavelength in air. (b) In a particular case, the incident light has a wavelength of 550 nm. Find the minimum value of \( d \) for a quartz plate for which \( \theta = \pi/2 \). Such a plate is called a quarter-wave plate. Use values of \( n_O \) and \( n_E \) from Table 38.1.

![Figure P38.75](image)

76. A spy satellite can consist of a large-diameter concave mirror forming an image on a digital-camera detector and sending the picture to a ground receiver by radio waves. In effect, it is an astronomical telescope in orbit, looking down instead of up. (a) Can a spy satellite read a license plate? (b) Can it read the date on a dime? Argue for your answers by making an order-of-magnitude calculation, specifying the data you estimate.

77. Suppose the single slit in Figure 38.4 is 6.00 cm wide and in front of a microwave source operating at 7.50 GHz. (a) Calculate the angle for the first minimum in the diffraction pattern. (b) What is the relative intensity \( I/I_{\text{max}} \) at \( \theta = 15.0^\circ \)? (c) Assume two such sources, separated laterally by 20.0 cm, are behind the slit. What must be the maximum distance between the plane of the sources and the slit if the diffraction patterns are to be resolved? In this case, the approximation \( \sin \theta \approx \tan \theta \) is not valid because of the relatively small value of \( a/\lambda \).

78. In Figure P38.78, suppose the transmission axes of the left and right polarizing disks are perpendicular to each other. Also, let the center disk be rotated on the common axis with an angular speed \( \omega \). Show that if unpolarized light is incident on the left disk with an intensity \( I_{\text{max}} \), the intensity of the beam emerging from the right disk is

\[
I = \frac{1}{\pi} I_{\text{max}} (1 - \cos 4\omega t)
\]

This result means that the intensity of the emerging beam is modulated at a rate four times the rate of rotation of the center disk. Suggestion: Use the trigonometric identities \( \cos^2 \theta = \frac{1}{2} (1 + \cos 2\theta) \) and \( \sin^2 \theta = \frac{1}{2} (1 - \cos 2\theta) \).

![Figure P38.78](image)

79. Consider a light wave passing through a slit and propagating toward a distant screen. Figure P38.79 shows the intensity variation for the pattern on the screen. Give a mathematical argument that more than 90% of the transmitted energy is in the central maximum of the diffraction pattern. Suggestion: You are not expected to calculate the precise percentage, but explain the steps of your reasoning. You may use the identification

\[
\frac{1}{1^2} + \frac{1}{3^2} + \frac{1}{5^2} + \cdots = \frac{\pi^2}{8}
\]

![Figure P38.79](image)
Modern Physics

The Compact Muon Solenoid (CMS) Detector is part of the Large Hadron Collider at the European Laboratory for Particle Physics operated by CERN. It is one of several detectors that search for elementary particles. For a sense of scale, the green structure to the left of the detector and extending to the top is five stories high. (CERN)

At the end of the 19th century, many scientists believed they had learned most of what there was to know about physics. Newton’s laws of motion and theory of universal gravitation, Maxwell’s theoretical work in unifying electricity and magnetism, the laws of thermodynamics and kinetic theory, and the principles of optics were highly successful in explaining a variety of phenomena.

At the turn of the 20th century, however, a major revolution shook the world of physics. In 1900, Max Planck provided the basic ideas that led to the formulation of the quantum theory, and in 1905, Albert Einstein formulated his special theory of relativity. The excitement of the times is captured in Einstein’s own words: “It was a marvelous time to be alive.” Both theories were to have a profound effect on our understanding of nature. Within a few decades, they inspired new developments in the fields of atomic physics, nuclear physics, and condensed-matter physics.

In Chapter 39, we shall introduce the special theory of relativity. The theory provides us with a new and deeper view of physical laws. Although the predictions of this theory often violate our common sense, the theory correctly describes the results of experiments involving speeds near the speed of light. The extended version of this textbook, Physics for Scientists and Engineers with Modern Physics, covers the basic concepts of quantum mechanics and their application to atomic and molecular physics. In addition, we introduce condensed matter physics, nuclear physics, particle physics, and cosmology in the extended version.

Even though the physics that was developed during the 20th century has led to a multitude of important technological achievements, the story is still incomplete. Discoveries will continue to evolve during our lifetimes, and many of these discoveries will deepen or refine our understanding of nature and the Universe around us. It is still a “marvelous time to be alive.”
Our everyday experiences and observations involve objects that move at speeds much less than the speed of light. Newtonian mechanics was formulated by observing and describing the motion of such objects, and this formalism is very successful in describing a wide range of phenomena that occur at low speeds. Nonetheless, it fails to describe properly the motion of objects whose speeds approach that of light.

Experimentally, the predictions of Newtonian theory can be tested at high speeds by accelerating electrons or other charged particles through a large electric potential difference. For example, it is possible to accelerate an electron to a speed of $0.99c$ (where $c$ is the speed of light) by using a potential difference of several million volts. According to Newtonian mechanics, if the potential difference is increased by a factor of 4, the electron’s kinetic energy is four times greater and its speed should double to $1.98c$. Experiments show, however, that the speed of the electron—as well as the speed of any other object in the Universe—always remains less than the speed of light, regardless of the size of the accelerating voltage. Because it places no upper limit on speed, Newtonian mechanics is contrary to modern experimental results and is clearly a limited theory.

In 1905, at the age of only 26, Einstein published his special theory of relativity. Regarding the theory, Einstein wrote:
The relativity theory arose from necessity, from serious and deep contradictions in the old theory from which there seemed no escape. The strength of the new theory lies in the consistency and simplicity with which it solves all these difficulties.¹

Although Einstein made many other important contributions to science, the special theory of relativity alone represents one of the greatest intellectual achievements of all time. With this theory, experimental observations can be correctly predicted over the range of speeds from \( v = 0 \) to speeds approaching the speed of light. At low speeds, Einstein's theory reduces to Newtonian mechanics as a limiting situation. It is important to recognize that Einstein was working on electromagnetism when he developed the special theory of relativity. He was convinced that Maxwell's equations were correct, and to reconcile them with one of his postulates, he was forced into the revolutionary notion of assuming that space and time are not absolute.

This chapter gives an introduction to the special theory of relativity, with emphasis on some of its predictions. In addition to its well-known and essential role in theoretical physics, the special theory of relativity has practical applications, including the design of nuclear power plants and modern global positioning system (GPS) units. These devices depend on relativistic principles for proper design and operation.

### 39.1 The Principle of Galilean Relativity

To describe a physical event, we must establish a frame of reference. You should recall from Chapter 5 that an inertial frame of reference is one in which an object is observed to have no acceleration when no forces act on it. Furthermore, any frame moving with constant velocity with respect to an inertial frame must also be an inertial frame.

There is no absolute inertial reference frame. Therefore, the results of an experiment performed in a vehicle moving with uniform velocity must be identical to the results of the same experiment performed in a stationary vehicle. The formal statement of this result is called the **principle of Galilean relativity:**

> The laws of mechanics must be the same in all inertial frames of reference.

Let's consider an observation that illustrates the equivalence of the laws of mechanics in different inertial frames. The pickup truck in Figure 39.1a moves with a

---

constant velocity with respect to the ground. If a passenger in the truck throws a ball straight up and if air resistance is neglected, the passenger observes that the ball moves in a vertical path. The motion of the ball appears to be precisely the same as if the ball were thrown by a person at rest on the Earth. The law of universal gravitation and the equations of motion under constant acceleration are obeyed whether the truck is at rest or in uniform motion.

Consider also an observer on the ground as in Figure 39.1b. Both observers agree on the laws of physics: the observer in the truck throws a ball straight up, and it rises and falls back into his hand according to the particle under constant acceleration model. Do the observers agree on the path of the ball thrown by the observer in the truck? The observer on the ground sees the path of the ball as a parabola as illustrated in Figure 39.1b, whereas, as mentioned earlier, the observer in the truck sees the ball move in a vertical path. Furthermore, according to the observer on the ground, the ball has a horizontal component of velocity equal to the velocity of the truck, and the horizontal motion of the ball is described by the particle under constant velocity model. Although the two observers disagree on certain aspects of the situation, they agree on the validity of Newton’s laws and on the results of applying appropriate analysis models that we have learned. This agreement implies that no mechanical experiment can detect any difference between the two inertial frames. The only thing that can be detected is the relative motion of one frame with respect to the other.

Quick Quiz 39.1 Which observer in Figure 39.1 sees the ball’s correct path? (a) the observer in the truck (b) the observer on the ground (c) both observers

Suppose some physical phenomenon, which we call an event, occurs and is observed by an observer at rest in an inertial reference frame. The wording “in a frame” means that the observer is at rest with respect to the origin of that frame. The event’s location and time of occurrence can be specified by the four coordinates \((x, y, z, t)\). We would like to be able to transform these coordinates from those of an observer in one inertial frame to those of another observer in a frame moving with uniform relative velocity compared with the first frame.

Consider two inertial frames \(S\) and \(S'\) (Fig. 39.2). The \(S'\) frame moves with a constant velocity \(\vec{v}\) along the common \(x\) and \(x'\) axes, where \(\vec{v}\) is measured relative to \(S\). We assume the origins of \(S\) and \(S'\) coincide at \(t = 0\) and an event occurs at point \(P\) in space at some instant of time. For simplicity, we show the observer \(O\) in the \(S\) frame and the observer \(O'\) in the \(S'\) frame as blue dots at the origins of their coordinate frames in Figure 39.2, but that is not necessary: either observer could be at any fixed location in his or her frame. Observer \(O\) describes the event with space–time coordinates \((x, y, z, t)\), whereas observer \(O'\) in \(S'\) uses the coordinates \((x', y', z', t')\) to describe the same event. Model the origin of \(S'\) as a particle under constant velocity relative to the origin of \(S\). As we see from the geometry in Figure 39.2, the relationships among these various coordinates can be written

\[
x' = x - vt \\
y' = y \\
z' = z \\
t' = t
\]

These equations are the **Galilean space–time transformation equations**. Note that time is assumed to be the same in both inertial frames. That is, within the framework of classical mechanics, all clocks run at the same rate, regardless of their velocity, so the time at which an event occurs for an observer in \(S\) is the same as the time for the same event in \(S'\). Consequently, the time interval between two successive events should be the same for both observers. Although this assumption may seem obvious, it turns out to be incorrect in situations where \(v\) is comparable to the speed of light.

Now suppose a particle moves through a displacement of magnitude \(dx\) along the \(x\) axis in a time interval \(dt\) as measured by an observer in \(S\). It follows from Equations 39.1 that the corresponding displacement \(dx'\) measured by an observer in \(S'\) is...
\[ dx' = dx - v \, dt, \] where frame \( S' \) is moving with speed \( v \) in the \( x \) direction relative to frame \( S \). Because \( dt = dt' \), we find that

\[ \frac{dx'}{dt'} = \frac{dx}{dt} - v \]

or

\[ u'_x = u_x - v \quad (39.2) \]

where \( u_x \) and \( u'_x \) are the \( x \) components of the velocity of the particle measured by observers in \( S \) and \( S' \), respectively. (We use the symbol \( \vec{u} \) rather than \( \vec{v} \) for particle velocity because \( \vec{v} \) is already used for the relative velocity of two reference frames.)

Equation 39.2 is the Galilean velocity transformation equation. It is consistent with our intuitive notion of time and space as well as with our discussions in Section 4.6. As we shall soon see, however, it leads to serious contradictions when applied to electromagnetic waves.

**Quick Quiz 39.2** A baseball pitcher with a 90-mi/h fastball throws a ball while standing on a railroad flatcar moving at 110 mi/h. The ball is thrown in the same direction as that of the velocity of the train. If you apply the Galilean velocity transformation equation to this situation, is the speed of the ball relative to the Earth (a) 90 mi/h, (b) 110 mi/h, (c) 20 mi/h, (d) 200 mi/h, or (e) impossible to determine?

---

**The Speed of Light**

It is quite natural to ask whether the principle of Galilean relativity also applies to electricity, magnetism, and optics. Experiments indicate that the answer is no. Recall from Chapter 34 that Maxwell showed that the speed of light in free space is \( c = 3.00 \times 10^8 \) m/s. Physicists of the late 1800s thought light waves move through a medium called the *ether* and the speed of light is \( c \) only in a special, absolute frame at rest with respect to the ether. The Galilean velocity transformation equation was expected to hold for observations of light made by an observer in any frame moving at speed \( v \) relative to the absolute ether frame. That is, if light travels along the \( x \) axis and an observer moves with velocity \( \vec{v} \) along the \( x \) axis, the observer measures the light to have speed \( c \pm v \), depending on the directions of travel of the observer and the light.

Because the existence of a preferred, absolute ether frame would show that light is similar to other classical waves and that Newtonian ideas of an absolute frame are true, considerable importance was attached to establishing the existence of the ether frame. Prior to the late 1800s, experiments involving light traveling in media moving at the highest laboratory speeds attainable at that time were not capable of detecting differences as small as that between \( c \) and \( c \pm v \). Starting in about 1880, scientists decided to use the Earth as the moving frame in an attempt to improve their chances of detecting these small changes in the speed of light.

Observers fixed on the Earth can take the view that they are stationary and that the absolute ether frame containing the medium for light propagation moves past them with speed \( v \). Determining the speed of light under these circumstances is similar to determining the speed of an aircraft traveling in a moving air current, or wind; consequently, we speak of an “ether wind” blowing through our apparatus fixed to the Earth.

A direct method for detecting an ether wind would use an apparatus fixed to the Earth to measure the ether wind’s influence on the speed of light. If \( v \) is the speed of the ether relative to the Earth, light should have its maximum speed \( c + v \) when propagating downwind as in Figure 39.3a. Likewise, the speed of light should have its minimum value \( c - v \) when the light is propagating upwind as in Figure 39.3b and an intermediate value \( (c^2 - v^2)^{1/2} \) when the light is directed such that it travels perpendicular to the ether wind as in Figure 39.3c. In this latter case, the vector \( \vec{c} \) is

---

**Pitfall Prevention 39.1**

**The Relationship Between the \( S \) and \( S' \) Frames** Many of the mathematical representations in this chapter are true only for the specified relationship between the \( S \) and \( S' \) frames. The \( x \) and \( x' \) axes coincide, except their origins are different. The \( y \) and \( y' \) axes (and the \( z \) and \( z' \) axes) are parallel, but they only coincide at one instant due to the time-varying position of the origin of \( S' \) with respect to that of \( S \). We choose the time \( t = 0 \) to be the instant at which the origins of the two coordinate systems coincide. If the \( S' \) frame is moving in the positive \( x \) direction relative to \( S \), then \( v \) is positive; otherwise, it is negative.

---

**Figure 39.3** If the velocity of the ether wind relative to the Earth is \( \vec{v} \) and the velocity of light relative to the ether is \( \vec{c} \), the speed of light relative to the Earth depends on the direction of the Earth’s velocity.
must be aimed upstream so that the resultant velocity is perpendicular to the wind, like the boat in Figure 4.21b. If the Sun is assumed to be at rest in the ether, the velocity of the ether wind would be equal to the orbital velocity of the Earth around the Sun, which has a magnitude of approximately 30 km/s or $3 \times 10^4$ m/s. Because $c = 3 \times 10^8$ m/s, it is necessary to detect a change in speed of approximately 1 part in $10^4$ for measurements in the upwind or downwind directions. Although such a change is experimentally measurable, all attempts to detect such changes and establish the existence of the ether wind (and hence the absolute frame) proved futile! We shall discuss the classic experimental search for the ether in Section 39.2.

The principle of Galilean relativity refers only to the laws of mechanics. If it is assumed the laws of electricity and magnetism are the same in all inertial frames, a paradox concerning the speed of light immediately arises. That can be understood by recognizing that Maxwell’s equations imply that the speed of light always has the fixed value $3.00 \times 10^8$ m/s in all inertial frames, a result in direct contradiction to what is expected based on the Galilean velocity transformation equation. According to Galilean relativity, the speed of light should be the same in all inertial frames.

To resolve this contradiction in theories, we must conclude that either (1) the laws of electricity and magnetism are not the same in all inertial frames or (2) the Galilean velocity transformation equation is incorrect. If we assume the first alternative, a preferred reference frame in which the speed of light has the value $c$ must exist and the measured speed must be greater or less than this value in any other reference frame, in accordance with the Galilean velocity transformation equation. If we assume the second alternative, we must abandon the notions of absolute time and absolute length that form the basis of the Galilean space–time transformation equations.

### 39.2 The Michelson–Morley Experiment

The most famous experiment designed to detect small changes in the speed of light was first performed in 1881 by A. A. Michelson (see Section 37.6) and later repeated under various conditions by Michelson and Edward W. Morley (1838–1923). As we shall see, the outcome of the experiment contradicted the ether hypothesis.

The experiment was designed to determine the velocity of the Earth relative to that of the hypothetical ether. The experimental tool used was the Michelson interferometer, which was discussed in Section 37.6 and is shown again in Figure 39.4. Arm 2 is aligned along the direction of the Earth’s motion through space. The Earth moving through the ether at speed $v$ is equivalent to the ether flowing past the Earth in the opposite direction with speed $v$. This ether wind blowing in the direction opposite the direction of the Earth’s motion should cause the speed of light measured in the Earth frame to be $c - v$ as the light approaches mirror $M_2$ and $c + v$ after reflection, where $c$ is the speed of light in the ether frame.

The two light beams reflect from $M_1$ and $M_2$ and recombine, and an interference pattern is formed as discussed in Section 37.6. The interference pattern is then observed while the interferometer is rotated through an angle of 90°. This rotation interchanges the speed of the ether wind between the arms of the interferometer. The rotation should cause the fringe pattern to shift slightly but measurably. Measurements failed, however, to show any change in the interference pattern! The Michelson–Morley experiment was repeated at different times of the year when the ether wind was expected to change direction and magnitude, but the results were always the same: no fringe shift of the magnitude required was ever observed.²

The negative results of the Michelson–Morley experiment not only contradicted the ether hypothesis, but also showed that it is impossible to measure the absolute

²From an Earth-based observer’s point of view, changes in the Earth’s speed and direction of motion in the course of a year are viewed as ether wind shifts. Even if the speed of the Earth with respect to the ether were zero at some time, six months later the speed of the Earth would be 60 km/s with respect to the ether and as a result a fringe shift should be noticed. No shift has ever been observed, however.
velocity of the Earth with respect to the ether frame. Einstein, however, offered a postulate for his special theory of relativity that places quite a different interpretation on these null results. In later years, when more was known about the nature of light, the idea of an ether that permeates all of space was abandoned. Light is now understood to be an electromagnetic wave, which requires no medium for its propagation. As a result, the idea of an ether in which these waves travel became unnecessary.

Details of the Michelson–Morley Experiment

To understand the outcome of the Michelson–Morley experiment, let’s assume the two arms of the interferometer in Figure 39.4 are of equal length $L$. We shall analyze the situation as if there were an ether wind because that is what Michelson and Morley expected to find. As noted above, the speed of the light beam along arm 2 should be $c - v$ as the beam approaches $M_2$ and $c + v$ after the beam is reflected. We model a pulse of light as a particle under constant speed. Therefore, the time interval for travel to the right for the pulse is $D_t = L/(c + v)$ and the time interval for travel to the left is $D_t = L/(c - v)$. The total time interval for the round trip along arm 2 is

$$D_{t_{arm2}} = \frac{L}{c + v} + \frac{L}{c - v} = \frac{2L}{c} \left(1 - \frac{v^2}{c^2}\right)^{-1}$$

Now consider the light beam traveling along arm 1, perpendicular to the ether wind. Because the speed of the beam relative to the Earth is $(c^2 - v^2)^{1/2}$ in this case (see Fig. 39.3c), the time interval for travel for each half of the trip is $D_t = L/(c^2 - v^2)^{1/2}$ and the total time interval for the round trip is

$$D_{t_{arm1}} = \frac{2L}{(c^2 - v^2)^{1/2}} = \frac{2Lc}{c^2} \left(1 - \frac{v^2}{c^2}\right)^{-1/2}$$

The time difference $\Delta t$ between the horizontal round trip (arm 2) and the vertical round trip (arm 1) is

$$\Delta t = D_{t_{arm2}} - D_{t_{arm1}} = \frac{2L}{c} \left(\left(1 - \frac{v^2}{c^2}\right)^{-1} - \left(1 - \frac{v^2}{c^2}\right)^{-1/2}\right)$$

Because $v^2/c^2 << 1$, we can simplify this expression by using the following binomial expansion after dropping all terms higher than second order:

$$(1 - x)^n \approx 1 - nx \quad \text{(for } x << 1\text{)}$$

In our case, $x = v^2/c^2$, and we find that

$$\Delta t \approx \frac{L}{c^3}$$

This time difference between the two instants at which the reflected beams arrive at the viewing telescope gives rise to a phase difference between the beams, producing an interference pattern when they combine at the position of the telescope. A shift in the interference pattern should be detected when the interferometer is rotated through $90^\circ$ in a horizontal plane so that the two beams exchange roles. This rotation results in a time difference twice that given by Equation 39.3. Therefore, the path difference that corresponds to this time difference is

$$\Delta d = c(2\Delta t) = \frac{2L\nu^2}{c^2}$$

Because a change in path length of one wavelength corresponds to a shift of one fringe, the corresponding fringe shift is equal to this path difference divided by the wavelength of the light:

$$\text{Shift} = \frac{2L\nu^2}{\lambda c^2}$$

(39.4)
In the experiments by Michelson and Morley, each light beam was reflected by mirrors many times to give an effective path length \( L \) of approximately 11 m. Using this value, taking \( v \) to be equal to \( 3.0 \times 10^4 \) m/s (the speed of the Earth around the Sun), and using 500 nm for the wavelength of the light, we expect a fringe shift of

\[
\text{Shift} = \frac{2(11 \text{ m})(3.0 \times 10^4 \text{ m/s})^2}{(5.0 \times 10^{-7} \text{ m})(3.0 \times 10^8 \text{ m/s})^2} = 0.44
\]

The instrument used by Michelson and Morley could detect shifts as small as 0.01 fringe, but it detected no shift whatsoever in the fringe pattern! The experiment has been repeated many times since by different scientists under a wide variety of conditions, and no fringe shift has ever been detected. Therefore, it was concluded that the motion of the Earth with respect to the postulated ether cannot be detected.

Many efforts were made to explain the null results of the Michelson–Morley experiment and to save the ether frame concept and the Galilean transformation equation for light. All proposals resulting from these efforts have been shown to be wrong. No experiment in the history of physics received such valiant efforts to explain the absence of an expected result as did the Michelson–Morley experiment. The stage was set for Einstein, who solved the problem in 1905 with his special theory of relativity.

### 39.3 Einstein’s Principle of Relativity

In the previous section, we noted the impossibility of measuring the speed of the ether with respect to the Earth and the failure of the Galilean velocity transformation equation in the case of light. Einstein proposed a theory that boldly removed these difficulties and at the same time completely altered our notion of space and time.\(^3\) He based his special theory of relativity on two postulates:

1. **The principle of relativity:** The laws of physics must be the same in all inertial reference frames.
2. **The constancy of the speed of light:** The speed of light in vacuum has the same value, \( c = 3.00 \times 10^8 \text{ m/s} \), in all inertial frames, regardless of the velocity of the observer or the velocity of the source emitting the light.

The first postulate asserts that all the laws of physics—those dealing with mechanics, electricity and magnetism, optics, thermodynamics, and so on—are the same in all reference frames moving with constant velocity relative to one another. This postulate is a generalization of the principle of Galilean relativity, which refers only to the laws of mechanics. From an experimental point of view, Einstein’s principle of relativity means that any kind of experiment (measuring the speed of light, for example) performed in a laboratory at rest must give the same result when performed in a laboratory moving at a constant velocity with respect to the first one. Hence, no preferred inertial reference frame exists, and it is impossible to detect absolute motion.

Note that postulate 2 is required by postulate 1: if the speed of light were not the same in all inertial frames, measurements of different speeds would make it possible to distinguish between inertial frames. As a result, a preferred, absolute frame could be identified, in contradiction to postulate 1.

Although the Michelson–Morley experiment was performed before Einstein published his work on relativity, it is not clear whether or not Einstein was aware of the details of the experiment. Nonetheless, the null result of the experiment can be readily understood within the framework of Einstein’s theory. According to

---

his principle of relativity, the premises of the Michelson–Morley experiment were incorrect. In the process of trying to explain the expected results, we stated that when light traveled against the ether wind, its speed was $c - v$, in accordance with the Galilean velocity transformation equation. If the state of motion of the observer or of the source has no influence on the value found for the speed of light, however, one always measures the value to be $c$. Likewise, the light makes the return trip after reflection from the mirror at speed $c$, not at speed $c + v$. Therefore, the motion of the Earth does not influence the interference pattern observed in the Michelson–Morley experiment, and a null result should be expected.

If we accept Einstein’s theory of relativity, we must conclude that relative motion is unimportant when measuring the speed of light. At the same time, we must alter our commonsense notion of space and time and be prepared for some surprising consequences. As you read the pages ahead, keep in mind that our commonsense ideas are based on a lifetime of everyday experiences and not on observations of objects moving at hundreds of thousands of kilometers per second. Therefore, these results may seem strange, but that is only because we have no experience with them.

### 39.4 Consequences of the Special Theory of Relativity

As we examine some of the consequences of relativity in this section, we restrict our discussion to the concepts of simultaneity, time intervals, and lengths, all three of which are quite different in relativistic mechanics from what they are in Newtonian mechanics. In relativistic mechanics, for example, the distance between two points and the time interval between two events depend on the frame of reference in which they are measured.

#### Simultaneity and the Relativity of Time

A basic premise of Newtonian mechanics is that a universal time scale exists that is the same for all observers. Newton and his followers took simultaneity for granted. In his special theory of relativity, Einstein abandoned this assumption.

Einstein devised the following thought experiment to illustrate this point. A boxcar moves with uniform velocity, and two bolts of lightning strike its ends as illustrated in Figure 39.5a, leaving marks on the boxcar and on the ground. The marks on the boxcar are labeled $A'$ and $B'$, and those on the ground are labeled $A$ and $B$. An observer $O'$ moving with the boxcar is midway between $A'$ and $B'$, and a ground observer $O$ is midway between $A$ and $B$. The events recorded by the observers are the striking of the boxcar by the two lightning bolts.

The light signals emitted from $A$ and $B$ at the instant at which the two bolts strike later reach observer $O$ at the same time as indicated in Figure 39.5b. This observer
realizes that the signals traveled at the same speed over equal distances and so concludes that the events at A and B occurred simultaneously. Now consider the same events as viewed by observer O. By the time the signals have reached observer O, observer O’ has moved as indicated in Figure 39.5b. Therefore, the signal from B’ has already swept past O’, but the signal from A’ has not yet reached O’. In other words, O’ sees the signal from B’ before seeing the signal from A’. According to Einstein, the two observers must find that light travels at the same speed. Therefore, observer O’ concludes that one lightning bolt strikes the front of the boxcar before the other one strikes the back.

This thought experiment clearly demonstrates that the two events that appear to be simultaneous to observer O do not appear to be simultaneous to observer O’. Simultaneity is not an absolute concept but rather one that depends on the state of motion of the observer. Einstein’s thought experiment demonstrates that two observers can disagree on the simultaneity of two events. This disagreement, however, depends on the transit time of light to the observers and therefore does not demonstrate the deeper meaning of relativity. In relativistic analyses of high-speed situations, simultaneity is relative even when the transit time is subtracted out. In fact, in all the relativistic effects we discuss, we ignore differences caused by the transit time of light to the observers.

**Time Dilation**

To illustrate that observers in different inertial frames can measure different time intervals between a pair of events, consider a vehicle moving to the right with a speed \( v \) such as the boxcar shown in Figure 39.6a. A mirror is fixed to the ceiling of the vehicle, and observer O’ at rest in the frame attached to the vehicle holds a flashlight a distance \( d \) below the mirror. At some instant, the flashlight emits a pulse of light directed toward the mirror (event 1), and at some later time after reflecting from the mirror, the pulse arrives back at the flashlight (event 2). Observer O’ carries a clock and uses it to measure the time interval \( \Delta t_p \) between these two events. (The subscript \( p \) stands for proper, as we shall see in a moment.) We model the pulse of light as a particle under constant speed. Because the light pulse has a speed \( c \), the time interval required for the pulse to travel from O’ to the mirror and back is

\[
\Delta t_p = \frac{\text{distance traveled}}{\text{speed}} = \frac{2d}{c}
\]

(39.5)

This assumes that \( v \) is much smaller than \( c \). In fact, this would not be true if the vehicle were moving at a significant fraction of the speed of light. However, the motion of the vehicle has little effect because the speed \( c \) is so much greater than \( v \).
Now consider the same pair of events as viewed by observer \( O \) in a second frame at rest with respect to the ground as shown in Figure 39.6b. According to this observer, the mirror and the flashlight are moving to the right with a speed \( v \), and as a result, the sequence of events appears entirely different. By the time the light from the flashlight reaches the mirror, the mirror has moved to the right a distance \( v \Delta t/2 \), where \( \Delta t \) is the time interval required for the light to travel from \( O' \) to the mirror and back to \( O' \) as measured by \( O \). Observer \( O \) concludes that because of the motion of the vehicle, if the light is to hit the mirror, it must leave the flashlight at an angle with respect to the vertical direction. Comparing Figure 39.6a with Figure 39.6b, we see that the light must travel farther in part (b) than in part (a). (Notice that neither observer “knows” that he or she is moving. Each is at rest in his or her own inertial frame.)

According to the second postulate of the special theory of relativity, both observers must measure \( c \) for the speed of light. Because the light travels farther according to \( O \), the time interval \( \Delta t \) measured by \( O \) is longer than the time interval \( \Delta t_p \) measured by \( O' \). To obtain a relationship between these two time intervals, let’s use the right triangle shown in Figure 39.6c. The Pythagorean theorem gives

\[
\left( \frac{c \Delta t}{2} \right)^2 = \left( \frac{v \Delta t}{2} \right)^2 + d^2
\]

Solving for \( \Delta t \) gives

\[
\Delta t = \frac{2d}{\sqrt{c^2 - v^2}} = \frac{2d}{c \sqrt{1 - \frac{v^2}{c^2}}}
\]

(39.6)

Because \( \Delta t_p = 2d/c \), we can express this result as

\[
\Delta t = \frac{\Delta t_p}{\sqrt{1 - \frac{v^2}{c^2}}} = \gamma \Delta t_p
\]

(39.7)

\( \gamma \) is always greater than unity, Equation 39.7 shows that the time interval \( \Delta t \) measured by an observer moving with respect to a clock is longer than the time interval \( \Delta t_p \) measured by an observer at rest with respect to the clock. This effect is known as time dilation.

Time dilation is not observed in our everyday lives, which can be understood by considering the factor \( \gamma \). This factor deviates significantly from a value of 1 only for very high speeds as shown in Figure 39.7 and Table 39.1. For example, for a speed of \( 0.1c \), the value of \( \gamma \) is 1.005. Therefore, there is a time dilation of only 0.5% at

![Figure 39.7 Graph of \( \gamma \) versus \( v \). As the speed approaches that of light, \( \gamma \) increases rapidly.](image)
one-tenth the speed of light. Speeds encountered on an everyday basis are far slower than 0.1c, so we do not experience time dilation in normal situations.

The time interval $\Delta t_p$ in Equations 39.5 and 39.7 is called the **proper time interval**. (Einstein used the German term *Eigenzeit*, which means “own-time.”) In general, the proper time interval is the time interval between two events measured by an observer who sees the events occur at the same point in space.

If a clock is moving with respect to you, the time interval between ticks of the moving clock is observed to be longer than the time interval between ticks of an identical clock in your reference frame. Therefore, it is often said that a moving clock is measured to run more slowly than a clock in your reference frame by a factor $\gamma$. We can generalize this result by stating that all physical processes, including mechanical, chemical, and biological ones, are measured to slow down when those processes occur in a frame moving with respect to the observer. For example, the heartbeat of an astronaut moving through space keeps time with a clock inside the spacecraft. Both the astronaut’s clock and heartbeat are measured to slow down relative to a clock back on the Earth (although the astronaut would have no sensation of life slowing down in the spacecraft).

**Quick Quiz 39.3** Suppose the observer $O'$ on the train in Figure 39.6 aims her flashlight at the far wall of the boxcar and turns it on and off, sending a pulse of light toward the far wall. Both $O'$ and $O$ measure the time interval between when the pulse leaves the flashlight and when it hits the far wall. Which observer measures the proper time interval between these two events? (a) $O'$ (b) $O$ (c) both observers (d) neither observer

**Quick Quiz 39.4** A crew on a spacecraft watches a movie that is two hours long. The spacecraft is moving at high speed through space. Does an Earth-based observer watching the movie screen on the spacecraft through a powerful telescope measure the duration of the movie to be (a) longer than, (b) shorter than, or (c) equal to two hours?

Time dilation is a very real phenomenon that has been verified by various experiments involving natural clocks. One experiment reported by J. C. Hafele and R. E. Keating provided direct evidence of time dilation.\(^4\) Time intervals measured with four cesium atomic clocks in jet flight were compared with time intervals measured by Earth-based reference atomic clocks. To compare these results with theory, many factors had to be considered, including periods of speeding up and slowing down relative to the Earth, variations in direction of travel, and the weaker gravitational field experienced by the flying clocks than that experienced by the Earth-based clock. The results were in good agreement with the predictions of the special theory of relativity and were explained in terms of the relative motion between the Earth and the jet aircraft. In their paper, Hafele and Keating stated that “relative to the atomic time scale of the U.S. Naval Observatory, the flying clocks lost $59 \pm 10$ ns during the eastward trip and gained $273 \pm 7$ ns during the westward trip.”

Another interesting example of time dilation involves the observation of **muons**, unstable elementary particles that have a charge equal to that of the electron and a mass 207 times that of the electron. Muons can be produced by the collision of cosmic radiation with atoms high in the atmosphere. Slow-moving muons in the laboratory have a lifetime that is measured to be the proper time interval $\Delta t_p = 2.2 \mu$s. If we take 2.2 $\mu$s as the average lifetime of a muon and assume that muons created by cosmic radiation have a speed close to the speed of light, we find that these particles can travel a distance of approximately $(3.0 \times 10^5 \text{ m/s})(2.2 \times 10^{-6} \text{ s}) \approx 6.6 \times 10^2 \text{ m}$ before they decay (Fig. 39.8a). Hence, they are unlikely to reach the

surface of the Earth from high in the atmosphere where they are produced. Experiments show, however, that a large number of muons do reach the surface. The phenomenon of time dilation explains this effect. As measured by an observer on the Earth, the muons have a dilated lifetime equal to \( \gamma \Delta t_p \). For example, for \( v = 0.99c \), \( \gamma \approx 7.1 \), and \( \gamma \Delta t_p \approx 16 \mu s \). Hence, the average distance traveled by the muons in this time interval as measured by an observer on the Earth is approximately \((0.99)(3.0 \times 10^8 \text{ m/s})(16 \times 10^{-6} \text{ s}) \approx 4.8 \times 10^3 \text{ m}\) as indicated in Figure 39.8b.

In 1976, at the laboratory of the European Council for Nuclear Research (CERN) in Geneva, muons injected into a large storage ring reached speeds of approximately 0.999 \( 4c \). Electrons produced by the decaying muons were detected by counters around the ring, enabling scientists to measure the decay rate and hence the muon lifetime. The lifetime of the moving muons was measured to be approximately 30 times as long as that of the stationary muon, in agreement with the prediction of relativity to within two parts in a thousand.

Example 39.1  What Is the Period of the Pendulum?

The period of a pendulum is measured to be 3.00 s in the reference frame of the pendulum. What is the period when measured by an observer moving at a speed of 0.960\( c \) relative to the pendulum?

Solution

Conceptualize  Let’s change frames of reference. Instead of the observer moving at 0.960\( c \), we can take the equivalent point of view that the observer is at rest and the pendulum is moving at 0.960\( c \) past the stationary observer. Hence, the pendulum is an example of a clock moving at high speed with respect to an observer.

Categorize  Based on the Conceptualize step, we can categorize this example as a substitution problem involving relativistic time dilation.

The proper time interval, measured in the rest frame of the pendulum, is \( \Delta t_p = 3.00 \text{ s} \).

Use Equation 39.7 to find the dilated time interval:

\[
\Delta t = \gamma \Delta t_p = \frac{1}{\sqrt{1 - \frac{(0.960c)^2}{c^2}}} \Delta t_p = \frac{1}{\sqrt{1 - 0.9216}} \Delta t_p
\]

\[
= 3.57(3.00 \text{ s}) = 10.7 \text{ s}
\]
This result shows that a moving pendulum is indeed measured to take longer to complete a period than a pendulum at rest does. The period increases by a factor of $\gamma = 3.57$.

**What if the speed of the observer increases by 4.00%?** Does the dilated time interval increase by 4.00%?

**Answer** Based on the highly nonlinear behavior of $\gamma$ as a function of $v$ in Figure 39.7, we would guess that the increase in $D\tau$ would be different from 4.00%.

Find the new speed if it increases by 4.00%:

$$v_{\text{new}} = (1.040 \ 0)(0.960c) = 0.998 \ 4c$$

Perform the time dilation calculation again:

$$\Delta t = \gamma \Delta t_p = \frac{1}{\sqrt{1 - \frac{(0.998 \ 4c)^2}{c^2}}} \Delta t_p = \frac{1}{\sqrt{1 - 0.996 \ 8}} \Delta t_p$$

$$= 17.68(3.00 \ \text{s}) = 53.1 \ \text{s}$$

Therefore, the 4.00% increase in speed results in almost a 400% increase in the dilated time!

---

**Example 39.2 How Long Was Your Trip?**

Suppose you are driving your car on a business trip and are traveling at 30 m/s. Your boss, who is waiting at your destination, expects the trip to take 5.0 h. When you arrive late, your excuse is that the clock in your car registered the passage of 5.0 h but that you were driving fast and so your clock ran more slowly than the clock in your boss’s office. If your car clock actually did indicate a 5.0-h trip, how much time passed on your boss’s clock, which was at rest on the Earth?

**Conceptualize** The observer is your boss standing stationary on the Earth. The clock is in your car, moving at 30 m/s with respect to your boss.

**Categorize** The low speed of 30 m/s suggests we might categorize this problem as one in which we use classical concepts and equations. Based on the problem statement that the moving clock runs more slowly than a stationary clock, however, we categorize this problem as one involving time dilation.

**Analyze** The proper time interval, measured in the rest frame of the car, is $\Delta t_p = 5.0 \ \text{h}$.

Use Equation 39.8 to evaluate $\gamma$:

$$\gamma = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{1}{\sqrt{1 - \frac{(3.0 \times 10^8 \ \text{m/s})^2}{(3.0 \times 10^8 \ \text{m/s})^2}}} = \frac{1}{\sqrt{1 - 10^{-14}}}$$

If you try to determine this value on your calculator, you will probably obtain $\gamma = 1$. Instead, perform a binomial expansion:

$$\gamma = (1 - 10^{-14})^{-1/2} = 1 + \frac{1}{2}(10^{-14}) = 1 + 5.0 \times 10^{-15}$$

Use Equation 39.7 to find the dilated time interval measured by your boss:

$$\Delta t = \gamma \Delta t_p = (1 + 5.0 \times 10^{-15})(5.0 \ \text{h})$$

$$= 5.0 \ \text{h} + 2.5 \times 10^{-14} \ \text{h} = 5.0 \ \text{h} + 0.090 \ \text{ns}$$

**Finalize** Your boss’s clock would be only 0.090 ns ahead of your car clock. You might want to think of another excuse!

---

**The Twin Paradox**

An intriguing consequence of time dilation is the *twin paradox* (Fig. 39.9). Consider an experiment involving a set of twins named Speedo and Goslo. When they are 20 years old, Speedo, the more adventuresome of the two, sets out on an epic journey from the Earth to Planet X, located 20 light-years away. One light-year (ly) is the distance light travels through free space in 1 year. Furthermore, Speedo’s...
spacecraft is capable of reaching a speed of $0.95c$ relative to the inertial frame of his twin brother back home on the Earth. After reaching Planet X, Speedo becomes homesick and immediately returns to the Earth at the same speed $0.95c$. Upon his return, Speedo is shocked to discover that Goslo has aged 42 years and is now 62 years old. Speedo, on the other hand, has aged only 13 years.

The paradox is not that the twins have aged at different rates. Here is the apparent paradox. From Goslo’s frame of reference, he was at rest while his brother traveled at a high speed away from him and then came back. According to Speedo, however, he himself remained stationary while Goslo and the Earth raced away from him and then headed back. Therefore, we might expect Speedo to claim that Goslo ages more slowly than himself. The situation appears to be symmetrical from either twin’s point of view. Which twin actually ages more slowly?

The situation is actually not symmetrical. Consider a third observer moving at a constant speed relative to Goslo. According to the third observer, Goslo never changes inertial frames. Goslo’s speed relative to the third observer is always the same. The third observer notes, however, that Speedo accelerates during his journey when he slows down and starts moving back toward the Earth, changing reference frames in the process. From the third observer’s perspective, there is something very different about the motion of Goslo when compared to Speedo. Therefore, there is no paradox: only Goslo, who is always in a single inertial frame, can make correct predictions based on special relativity. Goslo finds that instead of aging 42 years, Speedo ages only $\sqrt{1 - v^2/c^2}(42 \text{ years}) = 13 \text{ years}$. Of these 13 years, Speedo spends 6.5 years traveling to Planet X and 6.5 years returning.

Quick Quiz 39.5 Suppose astronauts are paid according to the amount of time they spend traveling in space. After a long voyage traveling at a speed approaching $c$, would a crew rather be paid according to (a) an Earth-based clock, (b) their spacecraft’s clock, or (c) either clock?

Length Contraction

The measured distance between two points in space also depends on the frame of reference of the observer. The proper length $L_p$ of an object is the length measured by an observer at rest relative to the object. The length of an object measured by someone in a reference frame that is moving with respect to the object is always less than the proper length. This effect is known as length contraction.

To understand length contraction, consider a spacecraft traveling with a speed $v$ from one star to another. There are two observers: one on the Earth and the other in the spacecraft. The observer at rest on the Earth (and also assumed to be at rest with
respect to the two stars) measures the distance between the stars to be the proper length $L_p$. According to this observer, the time interval required for the spacecraft to complete the voyage is given by the particle under constant velocity model as $\Delta t = \frac{L_p}{v}$. The passages of the two stars occur at the same position for the space traveler. Therefore, the space traveler measures the proper time interval $\Delta t_p$. Because of time dilation, the proper time interval is related to the Earth-measured time interval by $\Delta t_p = \frac{\Delta t}{\gamma}$. Because the space traveler reaches the second star in the time $\Delta t_p$, he or she concludes that the distance $L$ between the stars is

$$L = v \Delta t = v \frac{\Delta t}{\gamma}$$

Because the proper length is $L_p = v \Delta t$, we see that

$$L = \frac{L_p}{\gamma} = L_p \sqrt{1 - \frac{v^2}{c^2}} \tag{39.9}$$

where $\sqrt{1 - \frac{v^2}{c^2}}$ is a factor less than unity. If an object has a proper length $L_p$ when it is measured by an observer at rest with respect to the object, its length $L$ when it moves with speed $v$ in a direction parallel to its length is measured to be shorter according to Equation 39.9.

For example, suppose a meterstick moves past a stationary Earth-based observer with speed $v$ as in Figure 39.10. The length of the meterstick as measured by an observer in a frame attached to the stick is the proper length $L_p$ shown in Figure 39.10a. The length of the stick $L$ measured by the Earth observer is shorter than $L_p$ by the factor $(1 - v^2/c^2)^{1/2}$ as suggested in Figure 39.10b. Notice that length contraction takes place only along the direction of motion.

The proper length and the proper time interval are defined differently. The proper length is measured by an observer for whom the endpoints of the length remain fixed in space. The proper time interval is measured by someone for whom the two events take place at the same position in space. As an example of this point, let’s return to the decaying muons moving at speeds close to the speed of light. An observer in the muon’s reference frame measures the proper lifetime, whereas an Earth-based observer measures the proper length (the distance between the creation point and the decay point in Fig. 39.8b). In the muon’s reference frame, there is no time dilation, but the distance of travel to the surface is shorter when measured in this frame. Likewise, in the Earth observer’s reference frame, there is time dilation, but the distance of travel is measured to be the proper length. Therefore, when calculations on the muon are performed in both frames, the outcome of the experiment in one frame is the same as the outcome in the other frame: more muons reach the surface than would be predicted without relativistic effects.

Quick Quiz 39.6 You are packing for a trip to another star. During the journey, you will be traveling at 0.99$c$. You are trying to decide whether you should buy smaller sizes of your clothing because you will be thinner on your trip due to length contraction. You also plan to save money by reserving a smaller cabin to sleep in because you will be shorter when you lie down. Should you (a) buy smaller sizes of clothing, (b) reserve a smaller cabin, (c) do neither of these things, or (d) do both of these things?

Quick Quiz 39.7 You are observing a spacecraft moving away from you. You measure it to be shorter than when it was at rest on the ground next to you. You also see a clock through the spacecraft window, and you observe that the passage of time on the clock is measured to be slower than that of the watch on your wrist. Compared with when the spacecraft was on the ground, what do you measure if the spacecraft turns around and comes toward you at the same speed? (a) The spacecraft is measured to be longer, and the clock runs faster. (b) The spacecraft is measured to be longer, and the clock runs slower. (c) The spacecraft is
measured to be shorter, and the clock runs faster. (d) The spacecraft is measured to be shorter, and the clock runs slower.

Space–Time Graphs

It is sometimes helpful to represent a physical situation with a space–time graph, in which \( ct \) is the ordinate and position \( x \) is the abscissa. The twin paradox is displayed in such a graph in Figure 39.11 from Goslo’s point of view. A path through space–time is called a world-line. At the origin, the world-lines of Speedo (blue) and Goslo (green) coincide because the twins are in the same location at the same time. After Speedo leaves on his trip, his world-line diverges from that of his brother. Goslo’s world-line is vertical because he remains fixed in location. At Goslo and Speedo’s reunion, the two world-lines again come together. It would be impossible for Speedo to have a world-line that crossed the path of a light beam that left the Earth when he did. To do so would require him to have a speed greater than \( c \) (which, as shown in Sections 39.6 and 39.7, is not possible).

World-lines for light beams are diagonal lines on space–time graphs, typically drawn at 45° to the right or left of vertical (assuming the \( x \) and \( ct \) axes have the same scales), depending on whether the light beam is traveling in the direction of increasing or decreasing \( x \). All possible future events for Goslo and Speedo lie above the \( x \) axis and between the red-brown lines in Figure 39.11 because neither twin can travel faster than light. The only past events that Goslo and Speedo could have experienced occur between two similar 45° world-lines that approach the origin from below the \( x \) axis.

If Figure 39.11 is rotated about the \( ct \) axis, the red-brown lines sweep out a cone, called the light cone, which generalizes Figure 39.11 to two space dimensions. The \( y \) axis can be imagined coming out of the page. All future events for an observer at the origin must lie within the light cone. We can imagine another rotation that would generalize the light cone to three space dimensions to include \( z \), but because of the requirement for four dimensions (three space dimensions and time), we cannot represent this situation in a two-dimensional drawing on paper.

Example 39.3 A Voyage to Sirius

An astronaut takes a trip to Sirius, which is located a distance of 8 light-years from the Earth. The astronaut measures the time of the one-way journey to be 6 years. If the spaceship moves at a constant speed of 0.8 \( c \), how can the 8-ly distance be reconciled with the 6-year trip time measured by the astronaut?

Solution

Conceptualize An observer on the Earth measures light to require 8 years to travel between Sirius and the Earth. The astronaut measures a time interval for his travel of only 6 years. Is the astronaut traveling faster than light?

Categorize Because the astronaut is measuring a length of space between the Earth and Sirius that is in motion with respect to her, we categorize this example as a length contraction problem. We also model the astronaut as a particle under constant velocity.

Analyze The distance of 8 ly represents the proper length from the Earth to Sirius measured by an observer on the Earth seeing both objects nearly at rest.

Calculate the contracted length measured by the astronaut using Equation 39.9:

\[
L = \frac{8 \text{ ly}}{\gamma} = (8 \text{ ly}) \sqrt{1 - \frac{v^2}{c^2}} = (8 \text{ ly}) \sqrt{1 - \left(\frac{0.8c}{c}\right)^2} = 5 \text{ ly}
\]

Use the particle under constant velocity model to find the travel time measured on the astronaut’s clock:

\[
\Delta t = \frac{L}{v} = \frac{5 \text{ ly}}{0.8c} = \frac{5 \text{ ly}}{0.8(1 \text{ ly/yr})} = 6 \text{ yr}
\]

continued
Finalize Notice that we have used the value for the speed of light as \( c = 1 \text{ ly/yr} \). The trip takes a time interval shorter than 8 years for the astronaut because, to her, the distance between the Earth and Sirius is measured to be shorter.

**WHAT IF?** What if this trip is observed with a very powerful telescope by a technician in Mission Control on the Earth? At what time will this technician see that the astronaut has arrived at Sirius?

**Answer** The time interval the technician measures for the astronaut to arrive is

\[
\Delta t = \frac{L_p}{v} = \frac{8 \text{ ly}}{0.8c} = 10 \text{ yr}
\]

For the technician to see the arrival, the light from the scene of the arrival must travel back to the Earth and enter the telescope. This travel requires a time interval of

\[
\Delta t = \frac{L_p}{c} = \frac{8 \text{ ly}}{c} = 8 \text{ yr}
\]

Therefore, the technician sees the arrival after 10 yr + 8 yr = 18 yr. If the astronaut immediately turns around and comes back home, she arrives, according to the technician, 20 years after leaving, only 2 years after the technician saw her arrive! In addition, the astronaut would have aged by only 12 years.

### Example 39.4 The Pole-in-the-Barn Paradox

The twin paradox, discussed earlier, is a classic “paradox” in relativity. Another classic “paradox” is as follows. Suppose a runner moving at 0.75\(c\) carries a horizontal pole 15 m long toward a barn that is 10 m long. The barn has front and rear doors that are initially open. An observer on the ground can instantly and simultaneously close and open the two doors by remote control. When the runner and the pole are inside the barn, the ground observer closes and then opens both doors so that the runner and pole are momentarily captured inside the barn and then proceed to exit the barn from the back doorway. Do both the runner and the ground observer agree that the runner makes it safely through the barn?

**Solution**

**Conceptualize** From your everyday experience, you would be surprised to see a 15-m pole fit inside a 10-m barn, but we are becoming used to surprising results in relativistic situations.

**Categorize** The pole is in motion with respect to the ground observer so that the observer measures its length to be contracted, whereas the stationary barn has a proper length of 10 m. We categorize this example as a length contraction problem. The runner carrying the pole is modeled as a particle under constant velocity.

**Analyze** Use Equation 39.9 to find the contracted length of the pole according to the ground observer:

\[
L_{\text{pole}} = L_p \sqrt{1 - \frac{v^2}{c^2}} = (15 \text{ m}) \sqrt{1 - (0.75)^2} = 9.9 \text{ m}
\]

Therefore, the ground observer measures the pole to be slightly shorter than the barn and there is no problem with momentarily capturing the pole inside it. The “paradox” arises when we consider the runner’s point of view.

Use Equation 39.9 to find the contracted length of the barn according to the running observer:

\[
L_{\text{barn}} = L_p \sqrt{1 - \frac{v^2}{c^2}} = (10 \text{ m}) \sqrt{1 - (0.75)^2} = 6.6 \text{ m}
\]

Because the pole is in the rest frame of the runner, the runner measures it to have its proper length of 15 m. Now the situation looks even worse: How can a 15-m pole fit inside a 6.6-m barn? Although this question is the classic one that is often asked, it is not the question we have asked because it is not the important one. We asked, “Does the runner make it safely through the barn?”

The resolution of the “paradox” lies in the relativity of simultaneity. The closing of the two doors is measured to be simultaneous by the ground observer. Because the doors are at different positions, however, they do not close simulta-
necessarily as measured by the runner. The rear door closes and then opens first, allowing the leading end of the pole to exit. The front door of the barn does not close until the trailing end of the pole passes by.

We can analyze this “paradox” using a space–time graph. Figure 39.12a is a space–time graph from the ground observer’s point of view. We choose \( x = 0 \) as the position of the front doorway of the barn and \( t = 0 \) as the instant at which the leading end of the pole is located at the front doorway of the barn. The world-lines for the two doorways of the barn are separated by 10 m and are vertical because the barn is not moving relative to this observer. For the pole, we follow two tilted world-lines, one for each end of the moving pole. These world-lines are 9.9 m apart horizontally, which is the contracted length seen by the ground observer. As seen in Figure 39.12a, the pole is entirely within the barn at some time.

Figure 39.12b shows the space–time graph according to the runner. Here, the world-lines for the pole are separated by 15 m and are vertical because the pole is at rest in the runner’s frame of reference. The barn is hurtling toward the runner, so the world-lines for the front and rear doorways of the barn are tilted to the left. The world-lines for the barn are separated by 6.6 m, the contracted length as seen by the runner. The leading end of the pole leaves the rear doorway of the barn long before the trailing end of the pole enters the barn. Therefore, the opening of the rear door occurs before the closing of the front door.

From the ground observer’s point of view, use the particle under constant velocity model to find the time after \( t = 0 \) at which the trailing end of the pole enters the barn:

\[
(1) \quad t = \frac{\Delta x}{v} = \frac{9.9 \text{ m}}{0.75c} = \frac{13.2 \text{ m}}{c}
\]

From the runner’s point of view, use the particle under constant velocity model to find the time at which the leading end of the pole leaves the barn:

\[
(2) \quad t = \frac{\Delta x}{v} = \frac{6.6 \text{ m}}{0.75c} = \frac{8.8 \text{ m}}{c}
\]

Find the time at which the trailing end of the pole enters the front door of the barn:

\[
(3) \quad t = \frac{\Delta x}{v} = \frac{15 \text{ m}}{0.75c} = \frac{20 \text{ m}}{c}
\]

**Finalize** From Equation (1), the pole should be completely inside the barn at a time corresponding to \( ct = 13.2 \text{ m} \). This situation is consistent with the point on the \( ct \) axis in Figure 39.12a where the pole is inside the barn. From Equation (2), the leading end of the pole leaves the barn at \( ct = 8.8 \text{ m} \). This situation is consistent with the point on the \( ct \) axis in Figure 39.12b where the rear doorway of the barn arrives at the leading end of the pole. Equation (3) gives \( ct = 20 \text{ m} \), which agrees with the instant shown in Figure 39.12b at which the front doorway of the barn arrives at the trailing end of the pole.

**The Relativistic Doppler Effect**

Another important consequence of time dilation is the shift in frequency observed for light emitted by atoms in motion as opposed to light emitted by atoms at rest. This phenomenon, known as the Doppler effect, was introduced in Chapter 17 as it pertains to sound waves. In the case of sound, the velocity \( v_S \) of the source with
respect to the medium of propagation can be distinguished from the velocity $v_0$ of the observer with respect to the medium (the air). Light waves must be analyzed differently, however, because they require no medium of propagation, and no method exists for distinguishing the velocity of a light source from the velocity of the observer. The only measurable velocity is the relative velocity $v$ between the source and the observer.

If a light source and an observer approach each other with a relative speed $v$, the frequency $f'$ measured by the observer is

$$f' = \frac{\sqrt{1 + v/c}}{\sqrt{1 - v/c}} f$$  \hspace{1cm} (39.10)$$

where $f$ is the frequency of the source measured in its rest frame. This relativistic Doppler shift equation, unlike the Doppler shift equation for sound, depends only on the relative speed $v$ of the source and observer and holds for relative speeds as great as $c$. As you might expect, the equation predicts that $f' > f$ when the source and observer approach each other. We obtain the expression for the case in which the source and observer recede from each other by substituting negative values for $v$ in Equation 39.10.

The most spectacular and dramatic use of the relativistic Doppler effect is the measurement of shifts in the frequency of light emitted by a moving astronomical object such as a galaxy. Light emitted by atoms and normally found in the extreme violet region of the spectrum is shifted toward the red end of the spectrum for atoms in other galaxies, indicating that these galaxies are receding from us. American astronomer Edwin Hubble (1889–1953) performed extensive measurements of this red shift to confirm that most galaxies are moving away from us, indicating that the Universe is expanding.

### 39.5 The Lorentz Transformation Equations

Suppose two events occur at points $P$ and $Q$ and are reported by two observers, one at rest in a frame $S$ and another in a frame $S'$ that is moving to the right with speed $v$ as in Figure 39.13. The observer in $S$ reports the events with space–time coordinates $(x, y, z, t)$, and the observer in $S'$ reports the same events using the coordinates $(x', y', z', t')$. Equation 39.1 predicts that the distance between the two points in space at which the events occur does not depend on motion of the observer: $\Delta x = \Delta x'$. Because this prediction is contradictory to the notion of length contraction, the Galilean transformation is not valid when $v$ approaches the speed of light. In this section, we present the correct transformation equations that apply for all speeds in the range $0 < v < c$.

The equations that are valid for all speeds and that enable us to transform coordinates from $S$ to $S'$ are the Lorentz transformation equations:

$$x' = \gamma (x - vt) \hspace{1cm} y' = \gamma y \hspace{1cm} z' = z \hspace{1cm} t' = \gamma \left( t - \frac{vy}{c^2} \right)$$  \hspace{1cm} (39.11)$$

These transformation equations were developed by Hendrik A. Lorentz (1853–1928) in 1890 in connection with electromagnetism. It was Einstein, however, who recognized their physical significance and took the bold step of interpreting them within the framework of the special theory of relativity.

Notice the difference between the Galilean and Lorentz time equations. In the Galilean case, $t = t'$. In the Lorentz case, however, the value for $t'$ assigned to an event by an observer $O'$ in the $S'$ frame in Figure 39.13 depends both on the time $t$ and on the coordinate $x$ as measured by an observer $O$ in the $S$ frame, which is consistent with the notion that an event is characterized by four space–time coordinates $(x, y, z, t)$. In other words, in relativity, space and time are not separate concepts but rather are closely interwoven with each other.
If you wish to transform coordinates in the S' frame to coordinates in the S frame, simply replace $v$ by $-v$ and interchange the primed and unprimed coordinates in Equations 39.11:

\[
x = \gamma(x' + vt') \quad y = y' \quad z = z' \quad t = \gamma \left( t' + \frac{v}{c^2} x' \right) \quad (39.12)
\]

When $v \ll c$, the Lorentz transformation equations should reduce to the Galilean equations. As $v$ approaches zero, $v/c \ll 1$; therefore, $\gamma \to 1$ and Equations 39.11 indeed reduce to the Galilean space–time transformation equations in Equation 39.1.

In many situations, we would like to know the difference in coordinates between two events or the time interval between two events as seen by observers $O$ and $O'$. From Equations 39.11 and 39.12, we can express the differences between the four variables $x, x', t,$ and $t'$ in the form

\[
\begin{align*}
\Delta x' &= \gamma(\Delta x - v \Delta t) \\
\Delta t' &= \gamma \left( \Delta t - \frac{v}{c^2} \Delta x \right) \quad S \to S' \quad (39.13) \\

\Delta x &= \gamma(\Delta x' + v \Delta t') \\
\Delta t &= \gamma \left( \Delta t' + \frac{v}{c^2} \Delta x' \right) \quad S' \to S \quad (39.14)
\end{align*}
\]

where $\Delta x' = x' - x'$ and $\Delta t' = t' - t'$ are the differences measured by observer $O'$ and $\Delta x = x - x$ and $\Delta t = t - t$ are the differences measured by observer $O$. (We have not included the expressions for relating the $y$ and $z$ coordinates because they are unaffected by motion along the $x$ direction.\(^5\))

**Example 39.5** Simultaneity and Time Dilation Revisited

**(A)** Use the Lorentz transformation equations in difference form to show that simultaneity is not an absolute concept.

**SOLUTION**

**Conceptualize** Imagine two events that are simultaneous and separated in space as measured in the $S'$ frame such that $\Delta t' = 0$ and $\Delta x' \neq 0$. These measurements are made by an observer $O'$ who is moving with speed $v$ relative to $O$.

**Categorize** The statement of the problem tells us to categorize this example as one involving the use of the Lorentz transformation.

**Analyze** From the expression for $\Delta t$ given in Equation 39.14, find the time interval $\Delta t$ measured by observer $O$:

\[
\Delta t = \gamma \left( \Delta t' + \frac{v}{c^2} \Delta x' \right) = \gamma \left( 0 + \frac{v}{c^2} \Delta x' \right) = \gamma \frac{v}{c^2} \Delta x'
\]

**Finalize** The time interval for the same two events as measured by $O$ is nonzero, so the events do not appear to be simultaneous to $O$.

**(B)** Use the Lorentz transformation equations in difference form to show that a moving clock is measured to run more slowly than a clock that is at rest with respect to an observer.

**SOLUTION**

**Conceptualize** Imagine that observer $O'$ carries a clock that he uses to measure a time interval $\Delta t'$. He finds that two events occur at the same place in his reference frame ($\Delta x' = 0$) but at different times ($\Delta t' \neq 0$). Observer $O'$ is moving with speed $v$ relative to $O$.

---

\(^5\)Although relative motion of the two frames along the $x$ axis does not change the $y$ and $z$ coordinates of an object, it does change the $y$ and $z$ velocity components of an object moving in either frame as noted in Section 39.6.
Suppose two observers in relative motion with respect to each other are both observing an object’s motion. Previously, we defined an event as occurring at an instant of time. Now let’s interpret the “event” as the object’s motion. We know that the Galilean velocity transformation (Eq. 39.2) is valid for low speeds. How do the observers’ measurements of the velocity of the object relate to each other if the speed of the object or the relative speed of the observers is close to that of light?

Once again, $S'$ is our frame moving at a speed $v$ relative to $S$. Suppose an object has a velocity component $u'_x$ measured in the $S'$ frame, where

$$u'_x = \frac{dx'}{dt'}$$  \hspace{1cm} (39.15)

Using Equation 39.11, we have

$$dx' = \gamma(dx - v dt)$$

$$dt' = \gamma\left(dt - \frac{v}{c^2} dx\right)$$

Substituting these values into Equation 39.15 gives

$$u'_x = \frac{dx - v dt}{dt - \frac{v}{c^2} dx} = \frac{\frac{dx}{dt} - \frac{v}{c^2} \frac{dx}{dt}}{1 - \frac{v}{c^2} \frac{dx}{dt}}$$

The term $dx/dt$, however, is simply the velocity component $u_x$ of the object measured by an observer in $S$, so this expression becomes

$$u'_x = \frac{u_x - \frac{v}{c^2} u_x}{1 - \frac{v}{c^2} u_x}$$  \hspace{1cm} (39.16)

If the object has velocity components along the $y$ and $z$ axes, the components as measured by an observer in $S'$ are

$$u'_y = \frac{u_y}{\gamma\left(1 - \frac{u_x v}{c^2}\right)} \quad \text{and} \quad u'_z = \frac{u_z}{\gamma\left(1 - \frac{u_x v}{c^2}\right)}$$  \hspace{1cm} (39.17)

Notice that $u'_y$ and $u'_z$ do not contain the parameter $v$ in the numerator because the relative velocity is along the $x$ axis.

When $v$ is much smaller than $c$ (the nonrelativistic case), the denominator of Equation 39.16 approaches unity and so $u'_x = u_x - \frac{v}{c^2} u_x$, which is the Galilean veloc-
ity transformation equation. In another extreme, when \( u_x = c \), Equation 39.16 becomes

\[
u'_x = \frac{c - v}{1 - \frac{cv}{c^2}} = c
\]

This result shows that a speed measured as \( c \) by an observer in S is also measured as \( c \) by an observer in \( S' \), independent of the relative motion of S and \( S' \). This conclusion is consistent with Einstein’s second postulate: the speed of light must be \( c \) relative to all inertial reference frames. Furthermore, we find that the speed of an object can never be measured as larger than \( c \). That is, the speed of light is the ultimate speed. We shall return to this point later.

To obtain \( u_x \) in terms of \( u'_x \), we replace \( v \) by \(-v\) in Equation 39.16 and interchange the roles of \( u_x \) and \( u'_x \):

\[
u_x = \frac{u'_x + v}{1 + \frac{u'_x v}{c^2}}
\]

(39.18)

Quick Quiz 39.8 You are driving on a freeway at a relativistic speed. (i) Straight ahead of you, a technician standing on the ground turns on a searchlight and a beam of light moves exactly vertically upward as seen by the technician. As you observe the beam of light, do you measure the magnitude of the vertical component of its velocity as (a) equal to \( c \), (b) greater than \( c \), or (c) less than \( c \)? (ii) If the technician aims the searchlight directly at you instead of upward, do you measure the magnitude of the horizontal component of its velocity as (a) equal to \( c \), (b) greater than \( c \), or (c) less than \( c \)?

Example 39.6 Relative Velocity of Two Spacecraft

Two spacecraft A and B are moving in opposite directions as shown in Figure 39.14. An observer on the Earth measures the speed of spacecraft A to be 0.750\(c\) and the speed of spacecraft B to be 0.850\(c\). Find the velocity of spacecraft B as observed by the crew on spacecraft A.

Solution

Conceptualize There are two observers, one (\( O \)) on the Earth and one (\( O' \)) on spacecraft A. The event is the motion of spacecraft B.

Categorize Because the problem asks to find an observed velocity, we categorize this example as one requiring the Lorentz velocity transformation.

Analyze The Earth-based observer at rest in the S frame makes two measurements, one of each spacecraft. We want to find the velocity of spacecraft B as measured by the crew on spacecraft A. Therefore, \( u_x = -0.850c \). The velocity of spacecraft A is also the velocity of the observer at rest in spacecraft A (the \( S' \) frame) relative to the observer at rest on the Earth. Therefore, \( v = 0.750c \).

Obtain the velocity \( u'_x \) of spacecraft B relative to spacecraft A using Equation 39.16:

\[
u'_x = \frac{u_x - v}{1 - \frac{u_x v}{c^2}} = \frac{-0.850c - 0.750c}{1 - (-0.850c)(0.750c)} = -0.977c
\]

Finalize The negative sign indicates that spacecraft B is moving in the negative x direction as observed by the crew on spacecraft A. Is that consistent with your expectation from Figure 39.14? Notice that the speed is less than \( c \). That is, an...
Example 39.7  Relativistic Leaders of the Pack

Two motorcycle pack leaders named David and Emily are racing at relativistic speeds along perpendicular paths as shown in Figure 39.15. How fast does Emily recede as seen by David over his right shoulder?

SOLUTION

Conceptualize The two observers are David and the police officer in Figure 39.15. The event is the motion of Emily. Figure 39.15 represents the situation as seen by the police officer at rest in frame S. Frame S’ moves along with David.

Categorize Because the problem asks to find an observed velocity, we categorize this problem as one requiring the Lorentz velocity transformation. The motion takes place in two dimensions.

Analyze Identify the velocity components for David and Emily according to the police officer:

David: \( v_x = 0.75c \quad v_y = 0 \)
Emily: \( u_x = 0 \quad u_y = -0.90c \)

Using Equations 39.16 and 39.17, calculate \( u'_x \) and \( u'_y \) for Emily as measured by David:

\[
\begin{align*}
    u'_x &= \frac{u_x - v}{\gamma} = \frac{0 - 0.75c}{\frac{1}{\sqrt{1 - (0.75c)^2}}} = -0.75c \\
    u'_y &= \frac{u_y}{\gamma} = \frac{-0.90c}{\frac{1}{\sqrt{1 - (0.75c)^2}}} = -0.60c
\end{align*}
\]

Using the Pythagorean theorem, find the speed of Emily as measured by David:

\[
    u' = \sqrt{(u'_x)^2 + (u'_y)^2} = \sqrt{(-0.75c)^2 + (-0.60c)^2} = 0.96c
\]

Finalize This speed is less than \( c \), as required by the special theory of relativity.

39.7 Relativistic Linear Momentum

To describe the motion of particles within the framework of the special theory of relativity properly, you must replace the Galilean transformation equations by the Lorentz transformation equations. Because the laws of physics must remain unchanged under the Lorentz transformation, we must generalize Newton’s laws and the definitions of linear momentum and energy to conform to the Lorentz
transformation equations and the principle of relativity. These generalized definitions should reduce to the classical (nonrelativistic) definitions for \( v \ll c \).

First, recall from the isolated system model that when two particles (or objects that can be modeled as particles) collide, the total momentum of the isolated system of the two particles remains constant. Suppose we observe this collision in a reference frame \( S \) and confirm that the momentum of the system is conserved. Now imagine that the momenta of the particles are measured by an observer in a second reference frame \( S' \) moving with velocity \( \vec{v} \) relative to the first frame. Using the Lorentz velocity transformation equation and the classical definition of linear momentum, \( \vec{p} = m \vec{u} \) (where \( \vec{u} \) is the velocity of a particle), we find that linear momentum of the system is not measured to be conserved by the observer in \( S' \). Because the laws of physics are the same in all inertial frames, however, linear momentum of the system must be conserved in all frames. We have a contradiction. In view of this contradiction and assuming the Lorentz velocity transformation equation is correct, we must modify the definition of linear momentum so that the momentum of an isolated system is conserved for all observers. For any particle, the correct relativistic equation for linear momentum that satisfies this condition is

\[
\vec{p} = m \vec{u} = \gamma m \vec{u}
\]

where \( m \) is the mass of the particle and \( \vec{u} \) is the velocity of the particle. When \( u \) is much less than \( c \), \( \gamma = \left(1 - \frac{u^2}{c^2}\right)^{-1/2} \) approaches unity and \( \vec{p} \) approaches \( m \vec{u} \). Therefore, the relativistic equation for linear momentum reduces to the classical expression when \( u \) is much smaller than \( c \), as it should.

The relativistic force \( \vec{F} \) acting on a particle whose linear momentum is \( \vec{p} \) is defined as

\[
\vec{F} = \frac{d \vec{p}}{dt}
\]

where \( \vec{p} \) is given by Equation 39.19. This expression, which is the relativistic form of Newton’s second law, is reasonable because it preserves classical mechanics in the limit of low velocities and is consistent with conservation of linear momentum for an isolated system \( (\vec{F}_{\text{ext}} = 0) \) both relativistically and classically.

It is left as an end-of-chapter problem (Problem 88) to show that under relativistic conditions, the acceleration \( \vec{a} \) of a particle decreases under the action of a constant force, in which case \( a \propto \left(1 - \frac{u^2}{c^2}\right)^{3/2} \). This proportionality shows that as the particle’s speed approaches \( c \), the acceleration caused by any finite force approaches zero. Hence, it is impossible to accelerate a particle from rest to a speed \( u \geq c \). This argument reinforces that the speed of light is the ultimate speed, the speed limit of the Universe. It is the maximum possible speed for energy transfer and for information transfer. Any object with mass must move at a lower speed.

**Example 39.8 Linear Momentum of an Electron**

An electron, which has a mass of \( 9.11 \times 10^{-31} \) kg, moves with a speed of \( 0.750c \). Find the magnitude of its relativistic momentum and compare this value with the momentum calculated from the classical expression.

**Solution**

**Conceptualize** Imagine an electron moving with high speed. The electron carries momentum, but the magnitude of its momentum is not given by \( p = mu \) because the speed is relativistic.

**Categorize** We categorize this example as a substitution problem involving a relativistic equation.

**continued**
39.8 continued

Use Equation 39.19 with \( u = 0.750c \) to find the magnitude of the momentum:

\[
p = \frac{m_u}{\sqrt{1 - \frac{u^2}{c^2}}}
\]

\[
p = \frac{(9.11 \times 10^{-31} \text{ kg})(0.750)(3.00 \times 10^8 \text{ m/s})}{\sqrt{1 - \frac{(0.750c)^2}{c^2}}}
\]

\[
= 3.10 \times 10^{-22} \text{ kg} \cdot \text{m/s}
\]

The classical expression (used incorrectly here) gives \( p_{\text{classical}} = m_u u = 2.05 \times 10^{-22} \text{ kg} \cdot \text{m/s} \). Hence, the correct relativistic result is 50% greater than the classical result!

39.8 Relativistic Energy

We have seen that the definition of linear momentum requires generalization to make it compatible with Einstein’s postulates. This conclusion implies that the definition of kinetic energy must most likely be modified also.

To derive the relativistic form of the work–kinetic energy theorem, imagine a particle moving in one dimension along the \( x \) axis. A force in the \( x \) direction causes the momentum of the particle to change according to Equation 39.20. In what follows, we assume the particle is accelerated from rest to some final speed \( u \).

The work done by the force \( F \) on the particle is

\[
W = \int_{x_1}^{x_2} F \, dx = \int_{t_1}^{t_2} \frac{dp}{dt} \, dt
\]

(39.21)

To perform this integration and find the work done on the particle and the relativistic kinetic energy as a function of \( u \), we first evaluate \( \frac{dp}{dt} \):

\[
\frac{dp}{dt} = \frac{d}{dt} \left( \frac{m_u}{\sqrt{1 - \frac{u^2}{c^2}}} \right) = \frac{m}{\left( \sqrt{1 - \frac{u^2}{c^2}} \right)^{3/2}} \frac{du}{dt}
\]

Substituting this expression for \( \frac{dp}{dt} \) and \( dx = u \, dt \) into Equation 39.21 gives

\[
W = \int_{0}^{t} \frac{m}{\left( 1 - \frac{u^2}{c^2} \right)^{3/2}} \left( u \, dt \right) = m \int_{0}^{u} \left( \frac{u}{1 - \frac{u^2}{c^2}} \right)^{3/2} \, du
\]

where we use the limits 0 and \( u \) in the integral because the integration variable has been changed from \( t \) to \( u \). Evaluating the integral gives

\[
W = \frac{mc^2}{\sqrt{1 - \frac{u^2}{c^2}}} - mc^2
\]

(39.22)

Recall from Chapter 7 that the work done by a force acting on a system consisting of a single particle equals the change in kinetic energy of the particle: \( W = \Delta K \). Because we assumed the initial speed of the particle is zero, its initial kinetic energy is zero, so \( W = K - K_i = K - 0 = K \). Therefore, the work \( W \) in Equation 39.22 is equivalent to the relativistic kinetic energy \( K \):

\[
K = \frac{mc^2}{\sqrt{1 - \frac{u^2}{c^2}}} = mc^2 - mc^2 = \gamma mc^2 - mc^2 = (\gamma - 1) mc^2
\]

(39.23)
This equation is routinely confirmed by experiments using high-energy particle accelerators.

At low speeds, where \( u/c \ll 1 \), Equation 39.23 should reduce to the classical expression \( K = \frac{1}{2}mu^2 \). We can check that by using the binomial expansion \( (1 - \beta^2)^{-1/2} \approx 1 + \frac{1}{2}\beta^2 + \cdots \) for \( \beta \ll 1 \), where the higher-order powers of \( \beta \) are neglected in the expansion. (In treatments of relativity, \( \beta \) is a common symbol used to represent \( u/c \) or \( v/c \).) In our case, \( \beta = u/c \), so

\[
\gamma = \frac{1}{\sqrt{1 - \frac{u^2}{c^2}}} = \left( 1 - \frac{u^2}{c^2} \right)^{-1/2} \approx 1 + \frac{1}{2}\frac{u^2}{c^2}
\]

Substituting this result into Equation 39.23 gives

\[
K = \left[ \left( 1 + \frac{1}{2}\frac{u^2}{c^2} \right) - 1 \right] mc^2 = \frac{1}{2}mu^2 \quad \text{(for } u/c \ll 1 \text{)}
\]

which is the classical expression for kinetic energy. A graph comparing the relativistic and nonrelativistic expressions is given in Figure 39.16. In the relativistic case, the particle speed never exceeds \( c \), regardless of the kinetic energy. The two curves are in good agreement when \( u \ll c \).

The constant term \( mc^2 \) in Equation 39.23, which is independent of the speed of the particle, is called the rest energy \( E_R \) of the particle:

\[
E_R = mc^2 \quad \text{(39.24)}
\]

Equation 39.24 shows that mass is a form of energy, where \( c^2 \) is simply a constant conversion factor. This expression also shows that a small mass corresponds to an enormous amount of energy, a concept fundamental to nuclear and elementary-particle physics.

The term \( \gamma mc^2 \) in Equation 39.23, which depends on the particle speed, is the sum of the kinetic and rest energies. It is called the total energy \( E \):

\[
\text{Total energy} = \text{kinetic energy} + \text{rest energy}
\]

\[
E = K + mc^2 \quad \text{(39.25)}
\]

or

\[
E = \left( \frac{mc^2}{\sqrt{1 - \frac{u^2}{c^2}}} \right) = \gamma mc^2 \quad \text{(39.26)}
\]

In many situations, the linear momentum or energy of a particle rather than its speed is measured. It is therefore useful to have an expression relating the total energy \( E \) to the relativistic linear momentum \( p \), which is accomplished by using the expressions \( E = \gamma mc^2 \) and \( p = \gamma mu \). By squaring these equations and subtracting, we can eliminate \( u \) (Problem 58). The result, after some algebra, is

\[
E^2 = p^2c^2 + \left( mc^2 \right)^2 \quad \text{(39.27)}
\]

When the particle is at rest, \( p = 0 \), so \( E = E_R = mc^2 \).

In Section 35.1, we introduced the concept of a particle of light, called a photon. For particles that have zero mass, such as photons, we set \( m = 0 \) in Equation 39.27 and find that

\[
E = pc \quad \text{(39.28)}
\]

\(^6\)One way to remember this relationship is to draw a right triangle having a hypotenuse of length \( E \) and legs of lengths \( pc \) and \( mc^2 \).
This equation is an exact expression relating total energy and linear momentum for photons, which always travel at the speed of light (in vacuum).

Finally, because the mass \( m \) of a particle is independent of its motion, \( m \) must have the same value in all reference frames. For this reason, \( m \) is often called the \textit{invariant mass}. On the other hand, because the total energy and linear momentum of a particle both depend on velocity, these quantities depend on the reference frame in which they are measured.

When dealing with subatomic particles, it is convenient to express their energy in electron volts (Section 25.1) because the particles are usually given this energy by acceleration through a potential difference. The conversion factor, as you recall from Equation 25.5, is

\[
1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}
\]

For example, the mass of an electron is \( 9.109 \times 10^{-31} \text{ kg} \). Hence, the rest energy of the electron is

\[
m_e c^2 = (9.109 \times 10^{-31} \text{ kg})(2.998 \times 10^8 \text{ m/s})^2 = 8.187 \times 10^{-14} \text{ J} \\
= (8.187 \times 10^{-14} \text{ J})(1 \text{ eV}/1.602 \times 10^{-19} \text{ J}) = 0.511 \text{ MeV}
\]

**Quick Quiz 39.9** The following \textit{pairs} of energies—particle 1: \( E, 2E \); particle 2: \( E, 3E \); particle 3: \( 2E, 4E \)—represent the rest energy and total energy of three different particles. Rank the particles from greatest to least according to their

- (a) mass,
- (b) kinetic energy, and
- (c) speed.

### Example 39.9 The Energy of a Speedy Proton

**Solution**

**Conceptualize** Even if the proton is not moving, it has energy associated with its mass. If it moves, the proton possesses more energy, with the total energy being the sum of its rest energy and its kinetic energy.

**Categorize** The phrase “rest energy” suggests we must take a relativistic rather than a classical approach to this problem.

**Analyze** Use Equation 39.24 to find the rest energy:

\[
E_R = m_pc^2 = (1.672 \times 10^{-27} \text{ kg})(2.998 \times 10^8 \text{ m/s})^2 \\
= (1.504 \times 10^{-10} \text{ J})(1.602 \times 10^{-19} \text{ J}) = 938 \text{ MeV}
\]

**Solution**

**B** If the total energy of a proton is three times its rest energy, what is the speed of the proton?

Use Equation 39.26 to relate the total energy of the proton to the rest energy:

\[
E = 3m_pc^2 = \frac{m_pc^2}{\sqrt{1 - \frac{u^2}{c^2}}} \rightarrow 3 = \frac{1}{\sqrt{1 - \frac{u^2}{c^2}}}
\]

Solve for \( u \):

\[
1 - \frac{u^2}{c^2} = \frac{1}{3} \rightarrow \frac{u^2}{c^2} = \frac{2}{3} \\
u = \sqrt{\frac{2}{3}} c = 0.943 c = 2.83 \times 10^8 \text{ m/s}
\]

**C** Determine the kinetic energy of the proton in units of electron volts.
Use Equation 39.25 to find the kinetic energy of the proton:

\[ K = E - m_p c^2 = 3m_p c^2 - m_p c^2 = 2m_p c^2 \]

\[ = 2(938 \text{ MeV}) = 1.88 \times 10^3 \text{ MeV} \]

(D) What is the proton’s momentum?

Use Equation 39.27 to calculate the momentum:

\[ E^2 = p^2 c^2 + (m_p c^2)^2 = (3m_p c^2)^2 \]

\[ p^2 c^2 = 9(m_p c^2)^2 - (m_p c^2)^2 = 8(m_p c^2)^2 \]

\[ p = \sqrt{\frac{m_p c^2}{c}} = \sqrt{\frac{938 \text{ MeV}}{c}} = 2.65 \times 10^3 \text{ MeV}/c \]

Finalize The unit of momentum in part (D) is written MeV/c, which is a common unit in particle physics. For comparison, you might want to solve this example using classical equations.

WHAT IF? In classical physics, if the momentum of a particle doubles, the kinetic energy increases by a factor of 4. What happens to the kinetic energy of the proton in this example if its momentum doubles?

Answer Based on what we have seen so far in relativity, it is likely you would predict that its kinetic energy does not increase by a factor of 4.

Find the new doubled momentum:

\[ p_{\text{new}} = 2 \left( \sqrt{\frac{m_p c^2}{c}} \right) = \sqrt{2} m_p c^2 \]

Use this result in Equation 39.27 to find the new total energy:

\[ E_{\text{new}}^2 = p_{\text{new}}^2 c^2 + (m_p c^2)^2 \]

\[ E_{\text{new}}^2 = \left( 4\sqrt{2} m_p c^2 \right)^2 + (m_p c^2)^2 = 33(m_p c^2)^2 \]

\[ E_{\text{new}} = \sqrt{33} m_p c^2 = 5.7 m_p c^2 \]

Use Equation 39.25 to find the new kinetic energy:

\[ K_{\text{new}} = E_{\text{new}} - m_p c^2 = 5.7 m_p c^2 - m_p c^2 = 4.7 m_p c^2 \]

This value is a little more than twice the kinetic energy found in part (C), not four times. In general, the factor by which the kinetic energy increases if the momentum doubles depends on the initial momentum, but it approaches 4 as the momentum approaches zero. In this latter situation, classical physics correctly describes the situation.

Equation 39.26, \( E = \gamma mc^2 \), represents the total energy of a particle. This important equation suggests that even when a particle is at rest (\( \gamma = 1 \)), it still possesses enormous energy through its mass. The clearest experimental proof of the equivalence of mass and energy occurs in nuclear and elementary-particle interactions in which the conversion of mass into kinetic energy takes place. Consequently, we cannot use the principle of conservation of energy in relativistic situations as it was outlined in Chapter 8. We must modify the principle by including rest energy as another form of energy storage.

This concept is important in atomic and nuclear processes, in which the change in mass is a relatively large fraction of the initial mass. In a conventional nuclear reactor, for example, the uranium nucleus undergoes fission, a reaction that results in several lighter fragments having considerable kinetic energy. In the case of \(^{235}\text{U} \), which is used as fuel in nuclear power plants, the fragments are two lighter nuclei and a few neutrons. The total mass of the fragments is less than that of the \(^{235}\text{U} \) by an amount \( \Delta m \). The corresponding energy \( \Delta mc^2 \) associated with this mass difference is
exactly equal to the sum of the kinetic energies of the fragments. The kinetic energy is absorbed as the fragments move through water, raising the internal energy of the water. This internal energy is used to produce steam for the generation of electricity.

Next, consider a basic fusion reaction in which two deuterium atoms combine to form one helium atom. The decrease in mass that results from the creation of one helium atom from two deuterium atoms is $\Delta m = 4.25 \times 10^{-29}$ kg. Hence, the corresponding energy that results from one fusion reaction is $\Delta mc^2 = 3.83 \times 10^{-12}$ J = 23.9 MeV. To appreciate the magnitude of this result, consider that if only 1 g of deuterium were converted to helium, the energy released would be on the order of $10^{12}$ J! In 2013's cost of electrical energy, this energy would be worth approximately $35,000. We shall present more details of these nuclear processes in Chapter 45 of the extended version of this textbook.

Example 39.10  Mass Change in a Radioactive Decay

The $^{216}$Po nucleus is unstable and exhibits radioactivity (Chapter 44). It decays to $^{212}$Pb by emitting an alpha particle, which is a helium nucleus, $^4$He. The relevant masses, in atomic mass units (see Table A.1 in Appendix A), are $m_i = m(^{216}$Po) = 216.001 915 u and $m_f = m(^{212}$Pb) + m($^4$He) = 211.991 898 u + 4.002 603 u.

(A) Find the mass change of the system in this decay.

\[ \Delta m = 216.001 \text{ u} - (211.991 \text{ u} + 4.002 \text{ u}) = 0.007 \text{ u} = 1.23 \times 10^{-29} \text{ kg} \]

(B) Find the energy this mass change represents.

\[ E = \Delta mc^2 = (1.23 \times 10^{-29} \text{ kg})(3.00 \times 10^8 \text{ m/s})^2 = 1.11 \times 10^{-12} \text{ J} = 6.92 \text{ MeV} \]

39.9  The General Theory of Relativity

Up to this point, we have sidestepped a curious puzzle. Mass has two seemingly different properties: a gravitational attraction for other masses and an inertial property that represents a resistance to acceleration. We first discussed these two attributes for mass in Section 5.5. To designate these two attributes, we use the subscripts $g$ and $i$ and write

\[
\begin{align*}
\text{Gravitational property:} & \quad F_g = m_g g \\
\text{Inertial property:} & \quad \sum F = m_i a
\end{align*}
\]

The value of the gravitational constant $G$ was chosen to make the magnitudes of $m_g$ and $m_i$ numerically equal. Regardless of how $G$ is chosen, however, the strict proportionality of $m_g$ and $m_i$ has been established experimentally to an extremely high degree: a few parts in $10^{12}$. Therefore, it appears that gravitational mass and inertial mass may indeed be exactly proportional.
Why, though? They seem to involve two entirely different concepts: a force of mutual gravitational attraction between two masses and the resistance of a single mass to being accelerated. This question, which puzzled Newton and many other physicists over the years, was answered by Einstein in 1916 when he published his theory of gravitation, known as the *general theory of relativity*. Because it is a mathematically complex theory, we offer merely a hint of its elegance and insight.

In Einstein’s view, the dual behavior of mass was evidence for a very intimate and basic connection between the two behaviors. He pointed out that no mechanical experiment (such as dropping an object) could distinguish between the two situations illustrated in Figures 39.17a and 39.17b. In Figure 39.17a, a person standing in an elevator on the surface of a planet feels pressed into the floor due to the gravitational force. If he releases his briefcase, he observes it moving toward the floor with acceleration \( g \). In Figure 39.17b, the person is in an elevator in empty space accelerating upward with \( a_{el} = +g_\hat{j} \). The person feels pressed into the floor with the same force as in Figure 39.17a. If he releases his briefcase, he observes it moving toward the floor with acceleration \( g \), exactly as in the previous situation. In each situation, an object released by the observer undergoes a downward acceleration of magnitude \( g \) relative to the floor. In Figure 39.17a, the person is at rest in an inertial frame in a gravitational field due to the planet. In Figure 39.17b, the person is in a noninertial frame accelerating in gravity-free space. Einstein’s claim is that these two situations are completely equivalent.

Einstein carried this idea further and proposed that no experiment, mechanical or otherwise, could distinguish between the two situations. This extension to include all phenomena (not just mechanical ones) has interesting consequences. For example, suppose a light pulse is sent horizontally across the elevator as in Figure 39.17c, in which the elevator is accelerating upward in empty space. From the point of view of an observer in an inertial frame outside the elevator, the light travels in a straight line while the floor of the elevator accelerates upward. According to the observer on the elevator, however, the trajectory of the light pulse bends downward as the floor of the elevator (and the observer) accelerates upward. Therefore, based on the equality of parts (a) and (b) of the figure, Einstein proposed that a

![Figure 39.17](image-url)
beam of light should also be bent downward by a gravitational field as in Figure 39.17d. Experiments have verified the effect, although the bending is small. A laser aimed at the horizon falls less than 1 cm after traveling 6,000 km. (No such bending is predicted in Newton’s theory of gravitation.)

Einstein’s **general theory of relativity** has two postulates:

- All the laws of nature have the same form for observers in any frame of reference, whether accelerated or not.
- In the vicinity of any point, a gravitational field is equivalent to an accelerated frame of reference in gravity-free space (the **principle of equivalence**).

One interesting effect predicted by the general theory is that time is altered by gravity. A clock in the presence of gravity runs slower than one located where gravity is negligible. Consequently, the frequencies of radiation emitted by atoms in the presence of a strong gravitational field are **redshifted** to lower frequencies when compared with the same emissions in the presence of a weak field. This gravitational redshift has been detected in spectral lines emitted by atoms in massive stars. It has also been verified on the Earth by comparing the frequencies of gamma rays emitted from nuclei separated vertically by about 20 m.

The second postulate suggests a gravitational field may be “transformed away” at any point if we choose an appropriate accelerated frame of reference, a freely falling one. Einstein developed an ingenious method of describing the acceleration necessary to make the gravitational field “disappear.” He specified a concept, the **curvature of space–time**, that describes the gravitational effect at every point. In fact, the curvature of space–time completely replaces Newton’s gravitational theory. According to Einstein, there is no such thing as a gravitational force. Rather, the presence of a mass causes a curvature of space–time in the vicinity of the mass, and this curvature dictates the space–time path that all freely moving objects must follow.

As an example of the effects of curved space–time, imagine two travelers moving on parallel paths a few meters apart on the surface of the Earth and maintaining an exact northward heading along two longitude lines. As they observe each other near the equator, they will claim that their paths are exactly parallel. As they approach the North Pole, however, they notice that they are moving closer together and will meet at the North Pole. Therefore, they claim that they moved along parallel paths, but moved toward each other, *as if there were an attractive force between them*. The travelers make this conclusion based on their everyday experience of moving on flat surfaces. From our mental representation, however, we realize they are walking on a curved surface, and it is the geometry of the curved surface, rather than an attractive force, that causes them to converge. In a similar way, general relativity replaces the notion of forces with the movement of objects through curved space–time.

One prediction of the general theory of relativity is that a light ray passing near the Sun should be deflected in the curved space–time created by the Sun’s mass. This prediction was confirmed when astronomers detected the bending of starlight near the Sun during a total solar eclipse that occurred shortly after World War I (Fig. 39.18). When this discovery was announced, Einstein became an international celebrity.
If the concentration of mass becomes very great as is believed to occur when a large star exhausts its nuclear fuel and collapses to a very small volume, a black hole may form as discussed in Chapter 13. Here, the curvature of space–time is so extreme that within a certain distance from the center of the black hole all matter and light become trapped as discussed in Section 13.6.

### Summary

#### Definitions

- **The relativistic expression for the linear momentum** of a particle moving with a velocity \( \mathbf{\bar{u}} \) is
  \[
  \mathbf{\bar{p}} = \frac{m \mathbf{\bar{u}}}{\sqrt{1 - \frac{u^2}{c^2}}} = \gamma m \mathbf{\bar{u}} \quad (39.19)
  \]

- **The relativistic force** \( \mathbf{\bar{F}} \) acting on a particle whose linear momentum is \( \mathbf{\bar{p}} \) is defined as
  \[
  \mathbf{\bar{F}} = \frac{d\mathbf{\bar{p}}}{dt} \quad (39.20)
  \]

#### Concepts and Principles

- **The two basic postulates of the special theory of relativity are as follows:**
  - The laws of physics must be the same in all inertial reference frames.
  - The speed of light in vacuum has the same value, \( c = 3.00 \times 10^8 \) m/s, in all inertial frames, regardless of the velocity of the observer or the velocity of the source emitting the light.

- **Three consequences of the special theory of relativity are as follows:**
  - Events that are measured to be simultaneous for one observer are not necessarily measured to be simultaneous for another observer who is in motion relative to the first.
  - Clocks in motion relative to an observer are measured to run slower by a factor \( \gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2} \). This phenomenon is known as time dilation.
  - The lengths of objects in motion are measured to be shorter in the direction of motion by a factor \( 1/\gamma = (1 - v^2/c^2)^{1/2} \). This phenomenon is known as length contraction.

- **The relativistic force** \( \mathbf{\bar{F}} \) acting on a particle whose linear momentum is \( \mathbf{\bar{p}} \) is defined as

- **The relativistic form of the Lorentz velocity transformation equation** is
  \[
  u'_x = \gamma \left( u_x - v \right) \quad y' = y \quad z' = z \quad t' = \gamma \left( t - \frac{v}{c^2} x \right) \quad (39.11)
  \]
  where \( \gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2} \) and the \( S' \) frame moves in the \( x \) direction at speed \( v \) relative to the \( S \) frame.

- **The relativistic expression for the kinetic energy** of a particle is

  \[
  K = \frac{mc^2}{\sqrt{1 - \frac{u^2}{c^2}}} - mc^2 = (\gamma - 1) mc^2 \quad (39.23)
  \]

- **The total energy** \( E \) of a particle is given by

  \[
  E = \frac{mc^2}{\sqrt{1 - \frac{u^2}{c^2}}} = \gamma mc^2 \quad (39.26)
  \]

- **The constant term** \( mc^2 \) in Equation 39.23 is called the **rest energy** \( E_R \) of the particle:

  \[
  E_R = mc^2 \quad (39.24)
  \]

- **The relativistic linear momentum of a particle is related to its total energy through the equation**

  \[
  E^2 = p^2c^2 + (mc^2)^2 \quad (39.27)
  \]
1. (i) Does the speed of an electron have an upper limit? (a) yes, the speed of light \( c \) (b) yes, with another value \( \epsilon \) (c) no (ii) Does the magnitude of an electron’s momentum have an upper limit? (a) yes, \( m \epsilon \) (b) yes, with another value (c) no (iii) Does the electron’s kinetic energy have an upper limit? (a) yes, \( \frac{1}{2}m \epsilon^{2} \) (b) yes, \( \frac{\epsilon^{2}}{2}m \epsilon^{2} \) (c) yes, with another value (d) no

2. A spacecraft zooms past the Earth with a constant velocity. An observer on the Earth measures that an undamaged clock on the spacecraft is ticking at one-third the rate of an identical clock on the Earth. What does an observer on the spacecraft measure about the Earth-based clock’s ticking rate? (a) It runs more than three times faster than his own clock. (b) It runs three times faster than his own. (c) It runs at the same rate as his own. (d) It runs at one-third the rate of his own. (e) It runs at less than one-third the rate of his own.

3. As a car heads down a highway traveling at a speed \( v \) away from a ground observer, which of the following statements are true about the measured speed of the light beam from the car’s headlights? More than one statement may be correct. (a) The ground observer measures the light speed to be \( c + v \). (b) The driver measures the light speed to be \( c \). (c) The ground observer measures the light speed to be \( c \). (d) The driver measures the light speed to be \( c - v \). (e) The ground observer measures the light speed to be \( c - v \).

4. A spacecraft built in the shape of a sphere moves past an observer on the Earth with a speed of 0.500c. What shape does the observer measure for the spacecraft as it goes by? (a) a sphere (b) a cigar shape, elongated along the direction of motion (c) a round pillow shape, flattened along the direction of motion (d) a conical shape, pointing in the direction of motion

5. An astronaut is traveling in a spacecraft in outer space in a straight line at a constant speed of 0.500c. Which of the following effects would she experience? (a) She would feel heavier. (b) She would find it harder to breathe. (c) Her heart rate would change. (d) Some

Conceptual Questions

1. In several cases, a nearby star has been found to have a large planet orbiting about it, although light from the planet could not be seen separately from the starlight. Using the ideas of a system rotating about its center of mass and of the Doppler shift for light, explain how an astronomer could determine the presence of the invisible planet.

2. Explain why, when defining the length of a rod, it is necessary to specify that the positions of the ends of the rod are to be measured simultaneously.

3. A train is approaching you at very high speed as you stand next to the tracks. Just as an observer on the train passes you, you both begin to play the same recorded version of a Beethoven symphony on identical iPods. (a) According to you, whose iPod finishes the symphony first? (b) What If? According to the observer on the train, whose iPod finishes the symphony first? (c) Whose iPod actually finishes the symphony first?

4. List three ways our day-to-day lives would change if the speed of light were only 50 m/s.

5. How is acceleration indicated on a space–time graph?

6. (a) “Newtonian mechanics correctly describes objects moving at ordinary speeds, and relativistic mechanics correctly describes objects moving very fast.” (b) “Relativistic mechanics must make a smooth transition as
it reduces to Newtonian mechanics in a case in which
the speed of an object becomes small compared with
the speed of light.” Argue for or against statements (a)
and (b).

7. The speed of light in water is 230 Mm/s. Suppose an
electron is moving through water at 250 Mm/s. Does
that violate the principle of relativity? Explain.

8. A particle is moving at a speed less than $c/2$. If the
speed of the particle is doubled, what happens to its
momentum?

9. Give a physical argument that shows it is impossible to
accelerate an object of mass $m$ to the speed of light,
even with a continuous force acting on it.

10. Explain how the Doppler effect with microwaves is
used to determine the speed of an automobile.

11. It is said that Einstein, in his teenage years, asked the
question, “What would I see in a mirror if I carried it in
my hands and ran at a speed near that of light?” How
would you answer this question?

12. (i) An object is placed at a position $p > f$ from a con-
cave mirror as shown in Figure CQ39.12a, where $f$
is the focal length of the mirror. In a finite time inter-
val, the object is moved to the right to a position at the
focal point $F$ of the mirror. Show that the image of
the object moves at a speed greater than the speed of
light. (ii) A laser pointer is suspended in a horizontal
plane and set into rapid rotation as shown in Figure
CQ39.12b. Show that the spot of light it produces on
a distant screen can move across the screen at a speed
greater than the speed of light. (If you carry out this
experiment, make sure the direct laser light cannot
enter a person’s eyes.) (iii) Argue that the experiments
in parts (i) and (ii) do not invalidate the principle that
no material, no energy, and no information can move
faster than light moves in a vacuum.

13. With regard to reference frames, how does general rel-
ativity differ from special relativity?

14. Two identical clocks are in the same house, one
upstairs in a bedroom and the other downstairs in the
kitchen. Which clock runs slower? Explain.

Section 39.1  The Principle of Galilean Relativity

Problems 46–48, 50, 51, 53–54, and 79 in Chapter 4 can
be assigned with this section.

1. The truck in Figure P39.1 is moving at a speed of
10.0 m/s relative to the ground. The person on the
truck throws a baseball in the backward direction at a
speed of 20.0 m/s relative to the truck. What is the
velocity of the baseball as measured by the observer on
the ground?

2. In a laboratory frame of reference, an observer notes
that Newton’s second law is valid. Assume forces and
masses are measured to be the same in any reference
frame for speeds small compared with the speed of
light. (a) Show that Newton’s second law is also valid
for an observer moving at a constant speed, small
compared with the speed of light, relative to the
laboratory frame. (b) Show that Newton’s second law
is not valid in a reference frame moving past the labo-
rary frame with a con-
stant acceleration.

3. The speed of the Earth in
its orbit is 29.8 km/s. If that
is the magnitude of the
velocity $\vec{v}$ of the ether wind
in Figure P39.3, find the
angle $\phi$ between the velocity
of light $\vec{c}$ in vacuum and
the resultant velocity of
light if there were an ether.

---

**Figure P39.1**

**Figure P39.3**
4. A car of mass 2,000 kg moving with a speed of 20.0 m/s collides and locks together with a 1,500-kg car at rest at a stop sign. Show that momentum is conserved in a reference frame moving at 10.0 m/s in the direction of the moving car.

Section 39.2 The Michelson–Morley Experiment
Section 39.3 Einstein’s Principle of Relativity
Section 39.4 Consequences of the Special Theory of Relativity

Problem 82 in Chapter 4 can be assigned with this section.

5. A star is 5.00 ly from the Earth. At what speed must a spacecraft travel on its journey to the star such that the Earth–star distance measured in the frame of the spacecraft is 2.00 ly?

6. A meterstick moving at 0.900c relative to the Earth’s surface approaches an observer at rest with respect to the Earth’s surface. (a) What is the meterstick’s length as measured by the observer? (b) Qualitatively, how would the answer to part (a) change if the observer started running toward the meterstick?

7. At what speed does a clock move if it is measured to run at a rate one-half the rate of a clock at rest with respect to an observer?

8. A muon formed high in the Earth’s atmosphere is measured by an observer on the Earth’s surface to travel at speed v = 0.990c for a distance of 4.60 km before it decays into an electron, a neutrino, and an antineutrino (µ⁻ → e⁻ + ν + ¯ν). (a) For what time interval does the muon live as measured in its reference frame? (b) How far does the Earth travel as measured in the frame of the muon?

9. How fast must a meterstick be moving if its length is measured to shrink to 0.500 m?

10. An astronaut is traveling in a space vehicle moving at 0.500c relative to the Earth. The astronaut measures her pulse rate at 75.0 beats per minute. Signals generated by the astronaut’s pulse are radioed to the Earth when the vehicle is moving in a direction perpendicular to the line that connects the vehicle with an observer on the Earth. (a) What pulse rate does the Earth-based observer measure? (b) What If? What would be the pulse rate if the speed of the space vehicle were increased to 0.990c?

11. A physicist drives through a stop light. When he is pulled over, he tells the police officer that the Doppler shift made the red light of wavelength 650 nm appear green to him, with a wavelength of 520 nm. The police officer writes out a traffic citation for speeding. How fast was the physicist traveling, according to his own testimony?

12. A fellow astronaut passes by you in a spacecraft traveling at a high speed. The astronaut tells you that his craft is 20.0 m long and that the identical craft you are sitting in is 19.0 m long. According to your observations, (a) how long is your craft, (b) how long is the astronaut’s craft, and (c) what is the speed of the astronaut’s craft relative to your craft?

13. A deep-space vehicle moves away from the Earth with a speed of 0.800c. An astronaut on the vehicle measures a time interval of 3.00 s to rotate her body through 1.00 rev as she floats in the vehicle. What time interval is required for this rotation according to an observer on the Earth?

14. For what value of v does γ = 1.010? Observe that for speeds lower than this value, time dilation and length contraction are effects amounting to less than 1%.

15. A supertrain with a proper length of 100 m travels at a speed of 0.950c as it passes through a tunnel having a proper length of 50.0 m. As seen by a trackside observer, is the train ever completely within the tunnel? If so, by how much do the train’s ends clear the ends of the tunnel?

16. The average lifetime of a pi meson in its own frame of reference (i.e., the proper lifetime) is 2.6 × 10⁻⁸ s. If the meson moves with a speed of 0.98c, what is (a) its mean lifetime as measured by an observer on Earth, and (b) the average distance it travels before decaying, as measured by an observer on Earth? (c) What distance would it travel if time dilation did not occur?

17. An astronomer on the Earth observes a meteoroid in the southern sky approaching the Earth at a speed of 0.800c. At the time of its discovery the meteoroid is 20.0 ly from the Earth. Calculate (a) the time interval required for the meteoroid to reach the Earth as measured by the Earthbound astronomer, (b) this time interval as measured by a tourist on the meteoroid, and (c) the distance to the Earth as measured by the tourist.

18. A cube of steel has a volume of 1.00 cm³ and a mass of 8.00 g when at rest on the Earth. If this cube is now given a speed v = 0.900c, what is its density as measured by a stationary observer? Note that relativistic density is defined as E_R/c²V.

19. A spacecraft with a proper length of 300 m passes by an observer on the Earth. According to this observer, it takes 0.750 µs for the spacecraft to pass a fixed point. Determine the speed of the spacecraft as measured by the Earth-based observer.

20. A spacecraft with a proper length of Lₕ passes by an observer on the Earth. According to this observer, it takes a time interval Δt for the spacecraft to pass a fixed point. Determine the speed of the object as measured by the Earth-based observer.

21. A light source recedes from an observer with a speed vₑ that is small compared with c. (a) Show that the fractional shift in the measured wavelength is given by the approximate expression

\[ \frac{\Delta \lambda}{\lambda} \approx \frac{v_e}{c} \]

This phenomenon is known as the redshift because the visible light is shifted toward the red. (b) Spectroscopic measurements of light at λ = 397 nm coming from a galaxy in Ursa Major reveal a redshift of 20.0 nm. What is the recessional speed of the galaxy?
22. **Review.** In 1963, astronaut Gordon Cooper orbited the Earth 22 times. The press stated that for each orbit, he aged two-millionths of a second less than he would have had he remained on the Earth. (a) Assuming Cooper was 160 km above the Earth in a circular orbit, determine the difference in elapsed time between someone on the Earth and the orbiting astronaut for the 22 orbits. You may use the approximation \( \frac{1}{\sqrt{1 - x}} = 1 + \frac{x}{2} \) for small \( x \). (b) Did the press report accurate information? Explain.

23. Police radar detects the speed of a car (Fig. P39.23) as follows. Microwaves of a precisely known frequency are broadcast toward the car. The moving car reflects the microwaves with a Doppler shift. The reflected waves are received and combined with an attenuated version of the transmitted wave. Beats occur between the two microwave signals. The beat frequency is measured. (a) For an electromagnetic wave reflected back to its source from a mirror approaching at speed \( v \), show that the reflected wave has frequency
\[ f' = \frac{c + v}{c - v} f \]
where \( f \) is the source frequency. (b) Noting that \( v \) is much less than \( c \), show that the beat frequency can be written as \( f_{\text{beat}} = 2v/\lambda \). (c) What beat frequency is measured for a car speed of 30.0 m/s if the microwaves have frequency 10.0 GHz? (d) If the beat frequency measurement in part (c) is accurate to \( \pm 5.0 \) Hz, how accurate is the speed measurement?

24. The identical twins Speedo and Goslo join a migration from the Earth to Planet X, 20.0 ly away in a reference frame in which both planets are at rest. The twins, of the same age, depart at the same moment on different spacecraft. Speedo’s spacecraft travels steadily at 0.950c and Goslo’s at 0.750c. (a) Calculate the age difference between the twins after Goslo’s spacecraft lands on Planet X. (b) Which twin is older?

25. An atomic clock moves at 1 000 km/h for 1.00 h as measured by an identical clock on the Earth. At the end of the 1.00-h interval, how many nanoseconds slow will the moving clock be compared with the Earth-based clock?

26. **Review.** An alien civilization occupies a planet circling a brown dwarf, several light-years away. The plane of the planet’s orbit is perpendicular to a line from the brown dwarf to the Sun, so the planet is at nearly a fixed position relative to the Sun. The extraterrestrials have come to love broadcasts of MacGyver, on television channel 2, at carrier frequency 57.0 MHz. Their line of sight to us is in the plane of the Earth’s orbit. Find the difference between the highest and lowest frequencies they receive due to the Earth’s orbital motion around the Sun.

### Section 39.5 The Lorentz Transformation Equations

27. A red light flashes at position \( x_R = 3.00 \) m and time \( t_R = 1.00 \times 10^{-3} \) s, and a blue light flashes at \( x_B = 5.00 \) m and \( t_B = 9.00 \times 10^{-3} \) s, all measured in the S reference frame. Reference frame \( S' \) moves uniformly to the right and has its origin at the same point as \( S \) at \( t = t' = 0 \). Both flashes are observed to occur at the same place in \( S' \). (a) Find the relative speed between \( S \) and \( S' \). (b) Find the location of the two flashes in frame \( S' \). (c) At what time does the red flash occur in the \( S' \) frame?

28. Shannon observes two light pulses to be emitted from the same location, but separated in time by 3.00 \( \mu \)s. Kimmie observes the emission of the same two pulses to be separated in time by 9.00 \( \mu \)s. (a) How fast is Kimmie moving relative to Shannon? (b) According to Kimmie, what is the separation in space of the two pulses?

29. A moving rod is observed to have a length of \( \ell = 2.00 \) m and to be oriented at an angle of \( \theta = 30.0^\circ \) with respect to the direction of motion as shown in Figure P39.29. The rod has a speed of 0.995c. (a) What is the proper length of the rod? (b) What is the orientation angle in the proper frame?

30. A rod moving with a speed \( v \) along the horizontal direction is observed to have length \( \ell \) and to make an angle \( \theta \) with respect to the direction of motion as shown in Figure P39.29. (a) Show that the length of the rod as measured by an observer at rest with respect to the rod is \( \ell_s = \ell [1 - (v^2/c^2) \cos^2 \theta]^{1/2} \). (b) Show that the angle \( \theta_s \), the rod makes with the \( x \) axis according to an observer at rest with respect to the rod can be found from \( \tan \theta_s = \gamma \tan \theta \). These results show that the rod is observed to be both contracted and rotated. (Take the lower end of the rod to be at the origin of the coordinate system in which the rod is at rest.)

31. Keilah, in reference frame \( S \), measures two events to be simultaneous. Event A occurs at the point (50.0 m, 0, 0) at the instant 9:00:00 Universal time on January 15,
2013. Event B occurs at the point (150 m, 0, 0) at the same moment. Torrey, moving past with a velocity of \(0.800c\), also observes the two events. In her reference frame \(S'\), which event occurred first and what time interval elapsed between the events?

**Section 39.6 The Lorentz Velocity Transformation Equations**

32. Figure P39.32 shows a jet of material (at the upper right) being ejected by galaxy M87 (at the lower left). Such jets are believed to be evidence of supermassive black holes at the center of a galaxy. Suppose two jets of material from the center of a galaxy are ejected in opposite directions. Both jets move at 0.750\(c\) relative to the galaxy center. Determine the speed of one jet relative to the other.

![Figure P39.32](image)

33. An enemy spacecraft moves away from the Earth at a speed of \(v = 0.800c\) (Fig. P39.33). A galactic patrol spacecraft pursues at a speed of \(u = 0.900c\) relative to the Earth. Observers on the Earth measure the patrol craft to be overtaking the enemy craft at a relative speed of 0.100\(c\). With what speed is the patrol craft overtaking the enemy craft as measured by the patrol craft’s crew?

![Figure P39.33](image)

34. A spacecraft is launched from the surface of the Earth with a velocity of 0.600\(c\) at an angle of 50.0° above the horizontal positive \(x\) axis. Another spacecraft is moving past with a velocity of 0.700\(c\) in the negative \(x\) direction. Determine the magnitude and direction of the velocity of the first spacecraft as measured by the pilot of the second spacecraft.

35. A rocket moves with a velocity of 0.92\(c\) to the right with respect to a stationary observer \(A\). An observer \(B\) moving relative to observer \(A\) finds that the rocket is moving with a velocity of 0.95\(c\) to the left. What is the velocity of observer \(B\) relative to observer \(A\)? (Hint: Consider observer \(B\)’s velocity in the frame of reference of the rocket.)

**Section 39.7 Relativistic Linear Momentum**

36. Calculate the momentum of an electron moving with a speed of (a) 0.010 \(c\), (b) 0.500 \(c\), and (c) 0.900 \(c\).

37. An electron has a momentum that is three times larger than its classical momentum. (a) Find the speed of the electron. (b) What if? How would your result change if the particle were a proton?

38. Show that the speed of an object having momentum of magnitude \(p\) and mass \(m\) is \(u = \frac{c}{\sqrt{1 + \left(\frac{mc}{p}\right)^2}}\).

39. (a) Calculate the classical momentum of a proton traveling at 0.990\(c\), neglecting relativistic effects. (b) Repeat the calculation while including relativistic effects. (c) Does it make sense to neglect relativity at such speeds?

40. The speed limit on a certain roadway is 90.0 km/h. Suppose speeding fines are made proportional to the amount by which a vehicle’s momentum exceeds the momentum it would have when traveling at the speed limit. The fine for driving at 190 km/h (that is, 100 km/h over the speed limit) is $80.0. What, then, is the fine for traveling (a) at 0.909 km/h? (b) At 1 000 000 090 km/h?

41. A golf ball travels with a speed of 90.0 m/s. By what fraction does its relativistic momentum magnitude \(p\) differ from its classical value \(mu\)? That is, find the ratio \((p - mu)/mu\).

42. The nonrelativistic expression for the momentum of a particle, \(p = mu\), agrees with experiment if \(u << c\). For what speed does the use of this equation give an error in the measured momentum of (a) 1.00% and (b) 10.0%?

43. An unstable particle at rest spontaneously breaks into two fragments of unequal mass. The mass of the first fragment is \(2.50 \times 10^{-28}\) kg, and that of the other is \(1.67 \times 10^{-27}\) kg. If the lighter fragment has a speed of 0.893\(c\) after the breakup, what is the speed of the heavier fragment?

**Section 39.8 Relativistic Energy**

44. Determine the energy required to accelerate an electron from (a) 0.500\(c\) to 0.900\(c\) and (b) 0.900\(c\) to 0.990\(c\).

45. An electron has a kinetic energy five times greater than its rest energy. Find (a) its total energy and (b) its speed.

46. Protons in an accelerator at the Fermi National Laboratory near Chicago are accelerated to a total energy that is 400 times their rest energy. (a) What is the speed of these protons in terms of \(c\)? (b) What is their kinetic energy in MeV?

47. A proton moves at 0.950\(c\). Calculate its (a) rest energy, (b) total energy, and (c) kinetic energy.

48. (a) Find the kinetic energy of a 78.0-kg spacecraft launched out of the solar system with speed 106 km/s
by using the classical equation $K = \frac{1}{2} mu^2$. (b) What If? Calculate its kinetic energy using the relativistic equation. (c) Explain the result of comparing the answers of parts (a) and (b).

A proton in a high-energy accelerator moves with a speed of $\frac{c}{2}$. Use the work–kinetic energy theorem to find the work required to increase its speed to (a) $0.750 c$ and (b) $0.995 c$.

50. Show that for any object moving at less than one-tenth the speed of light, the relativistic kinetic energy agrees with the result of the classical equation $K = \frac{1}{2} mu^2$ to within less than 1%. Therefore, for most purposes, the classical equation is sufficient to describe these objects.

The total energy of a proton is twice its rest energy. Find the momentum of the proton in MeV/c units.

Consider electrons accelerated to a total energy of 20.0 GeV in the 3.00-km-long Stanford Linear Accelerator. (a) What is the factor $\gamma$ for the electrons? (b) What is the electrons' speed at the given energy? (c) What is the length of the accelerator in the electrons' frame of reference when they are moving at their highest speed?

When 1.00 g of hydrogen combines with 8.00 g of oxygen, 9.00 g of water is formed. During this chemical reaction, $2.86 \times 10^7$ J of energy is released. (a) Is the mass of the water larger or smaller than the mass of the reactants? (b) What is the difference in mass? (c) Explain whether the change in mass is likely to be detectable.

In a nuclear power plant, the fuel rods last 3 yr before they are replaced. The plant can transform energy at a maximum possible rate of 1.00 GW. Supposing it operates at 80.0% capacity for 3.00 yr, what is the loss of mass of the fuel?

The power output of the Sun is $3.85 \times 10^{26}$ W. By how much does the mass of the Sun decrease each second?

A gamma ray (a high-energy photon) can produce an electron ($e^-$) and a positron ($e^+$) of equal mass when it enters the electric field of a heavy nucleus: $\gamma \rightarrow e^- + e^+$. What minimum gamma-ray energy is required to accomplish this task?

A spaceship of mass $2.40 \times 10^6$ kg is to be accelerated to a speed of $0.700c$. (a) What minimum amount of energy does this acceleration require from the spaceship’s fuel, assuming perfect efficiency? (b) How much fuel would it take to provide this much energy if all the rest energy of the fuel could be transformed to kinetic energy of the spaceship?

Show that the energy–momentum relationship in Equation 39.27, $E^2 = p^2c^2 + (mc^2)^2$, follows from the expressions $E = \gamma mc^2$ and $p = \gamma mu$.

The rest energy of an electron is 0.511 MeV. The rest energy of a proton is 938 MeV. Assume both particles have kinetic energies of 2.00 MeV. Find the speed of (a) the electron and (b) the proton. (c) By what factor does the speed of the electron exceed that of the proton? (d) Repeat the calculations in parts (a) through (c) assuming both particles have kinetic energies of 2.000 MeV.

Consider a car moving at highway speed $u$. Is its actual kinetic energy larger or smaller than $\frac{1}{2} mu^2$? Make an order-of-magnitude estimate of the amount by which its actual kinetic energy differs from $\frac{1}{2} mu^2$. In your solution, state the quantities you take as data and the values you measure or estimate for them. You may find Appendix B.5 useful.

A pion at rest ($m_\pi = 273 m_\mu$) decays to a muon ($m_\mu = 207m_\mu$) and an antineutrino ($m_\nu = 0$). The reaction is written $\pi^- \rightarrow \mu^- + \bar{\nu}$. Find (a) the kinetic energy of the muon and (b) the energy of the antineutrino in electron volts.

An unstable particle with mass $m = 3.34 \times 10^{-27}$ kg is initially at rest. The particle decays into two fragments that fly off along the $x$ axis with velocity components $u_1 = 0.987c$ and $u_2 = -0.868c$. From this information, we wish to determine the masses of fragments 1 and 2. (a) Is the initial system of the unstable particle, which becomes the system of the two fragments, isolated or nonisolated? (b) Based on your answer to part (a), what two analysis models are appropriate for this situation? (c) Find the values of $\gamma$ for the two fragments after the decay. (d) Using one of the analysis models in part (b), find a relationship between the masses $m_1$ and $m_2$ of the fragments. (e) Using the second analysis model in part (b), find a second relationship between the masses $m_1$ and $m_2$. (f) Solve the relationships in parts (d) and (e) simultaneously for the masses $m_1$ and $m_2$.

Massive stars ending their lives in supernova explosions produce the nuclei of all the atoms in the bottom half of the periodic table by fusion of smaller nuclei. This problem roughly models that process. A particle of mass $m = 1.99 \times 10^{-26}$ kg moving with a velocity $\mathbf{u} = 0.500\hat{z}$ collides head-on and sticks to a particle of mass $m' = m/3$ moving with the velocity $\mathbf{u}' = -0.500\hat{z}$. What is the mass of the resulting particle?

Massive stars ending their lives in supernova explosions produce the nuclei of all the atoms in the bottom half of the periodic table by fusion of smaller nuclei. This problem roughly models that process. A particle of mass $m$ moving along the $x$ axis with a velocity component $+u$ collides head-on and sticks to a particle of mass $m/3$ moving along the $x$ axis with the velocity component $-u$. (a) What is the mass $M$ of the resulting particle? (b) Evaluate the expression from part (a) in the limit $u \rightarrow 0$. (c) Explain whether the result agrees with what you should expect from nonrelativistic physics.

Section 39.9 The General Theory of Relativity

Review. A global positioning system (GPS) satellite moves in a circular orbit with period 11 h 58 min. (a) Determine the radius of its orbit. (b) Determine its speed. (c) The nonmilitary GPS signal is broadcast at a frequency of 1,575.42 MHz in the reference frame of the satellite. When it is received on the Earth’s surface by a GPS receiver (Fig. P39.65 on page 1230), what is
the fractional change in this frequency due to time dilation as described by special relativity? (d) The gravitational “blueshift” of the frequency according to general relativity is a separate effect. It is called a blueshift to indicate a change to a higher frequency. The magnitude of that fractional change is given by

$$\frac{\Delta f}{f} = \frac{\Delta U_g}{mc^2}$$

where \( U_g \) is the change in gravitational potential energy of an object–Earth system when the object of mass \( m \) is moved between the two points where the signal is observed. Calculate this fractional change in frequency due to the change in position of the satellite from the Earth’s surface to its orbital position. (c) What is the overall fractional change in frequency due to both time dilation and gravitational blueshift?

**Figure P39.65**

Additional Problems

66. An electron has a speed of 0.750c. (a) Find the speed of a proton that has the same kinetic energy as the electron. (b) What If? Find the speed of a proton that has the same momentum as the electron.

67. The net nuclear fusion reaction inside the Sun can be written as \(^4\text{H} \rightarrow ^4\text{He} + E\). The rest energy of each hydrogen atom is 938.78 MeV, and the rest energy of the helium-4 atom is 3 728.4 MeV. Calculate the percentage of the starting mass that is transformed to other forms of energy.

68. Why is the following situation impossible? On their 40th birthday, twins Speedo and Goslo say good-bye as Speedo takes off for a planet that is 50 ly away. He travels at a constant speed of 0.85c and immediately turns around and comes back to the Earth after arriving at the planet. Upon arriving back at the Earth, Speedo has a joyous reunion with Goslo.

69. A Doppler weather radar station broadcasts a pulse of radio waves at frequency 2.85 GHz. From a relatively small batch of raindrops at bearing 38.6° east of north, the station receives a reflected pulse after 180 \( \mu \)s with a frequency shifted upward by 254 Hz. From a similar batch of raindrops at bearing 39.6° east of north, the station receives a reflected pulse after the same time delay, with a frequency shifted downward by 254 Hz. These pulses have the highest and lowest frequencies the station receives. (a) Calculate the radial velocity components of both batches of raindrops. (b) Assume that these raindrops are swirling in a uniformly rotating vortex. Find the angular speed of their rotation.

70. An object having mass 900 kg and traveling at speed 0.850c collides with a stationary object having mass 1 400 kg. The two objects stick together. Find (a) the speed and (b) the mass of the composite object.

71. An astronaut wishes to visit the Andromeda galaxy, making a one-way trip that will take 30.0 years in the spaceship’s frame of reference. Assume the galaxy is 2.00 million light-years away and his speed is constant. (a) How fast must he travel relative to Earth? (b) What will be the kinetic energy of his spacecraft, which has mass of \( 1.00 \times 10^6 \) kg? (c) What is the cost of this energy if it is purchased at a typical consumer price for electric energy, 13.0¢ per kWh? The following approximation will prove useful:

$$\frac{1}{\sqrt{1 + x}} \approx 1 - \frac{x}{2} \text{ for } x << 1$$

72. A physics professor on the Earth gives an exam to her students, who are in a spacecraft traveling at speed \( v \) relative to the Earth. The moment the craft passes the professor, she signals the start of the exam. She wishes her students to have a time interval \( T_e \) (spacecraft time) to complete the exam. Show that she should wait a time interval (Earth time) of

$$T = T_e \sqrt{\frac{1 - v/c}{1 + v/c}}$$

before sending a light signal telling them to stop. (Suggestion: Remember that it takes some time for the second light signal to travel from the professor to the students.)

73. An interstellar space probe is launched from Earth. After a brief period of acceleration, it moves with a constant velocity, 70.0% of the speed of light. Its nuclear-powered batteries supply the energy to keep its data transmitter active continuously. The batteries have a lifetime of 15.0 years as measured in a rest frame. (a) How long do the batteries on the space probe last as measured by mission control on Earth? (b) How far is the probe from Earth when its batteries fail as measured by mission control? (c) How far is the probe from Earth as measured by its built-in trip odometer when its batteries fail? (d) For what total time after launch are data received from the probe by mission control? Note that radio waves travel at the speed of light and fill the space between the probe and Earth at the time the battery fails.

74. The equation

$$K = \left(\frac{1}{\sqrt{1 - u^2/c^2}} - 1\right)mc^2$$

gives the kinetic energy of a particle moving at speed \( u \). (a) Solve the equation for \( u \). (b) From the equation for \( u \), identify the minimum possible value of speed and the corresponding kinetic energy. (c) Identify
the maximum possible speed and the corresponding kinetic energy. (d) Differentiate the equation for $u$ with respect to time to obtain an equation describing the acceleration of a particle as a function of its kinetic energy and the power input to the particle. (e) Observe that for a nonrelativistic particle we have $u = (2K/m)^{1/2}$ and that differentiating this equation with respect to time gives $a = P/(2mK)^{1/2}$. State the limiting form of the expression in part (d) at low energy. State how it compares with the nonrelativistic expression. (f) State the limiting form of the expression in part (d) at high energy. (g) Consider a particle with constant input power. Explain how the answer to part (f) helps account for the answer to part (c).

75. Consider the astronaut planning the trip to Andromeda in Problem 71. (a) To three significant figures, what is the value for $\gamma$ for the speed found in part (a) of Problem 71? (b) Just as the astronaut leaves on his constant-speed trip, a light beam is also sent in the direction of Andromeda. According to the Earth observer, how much later does the astronaut arrive at Andromeda after the arrival of the light beam?

76. An object disintegrates into two fragments. One fragment has mass 1.00 MeV/$c^2$ and momentum 1.75 MeV/$c$ in the positive $x$ direction, and the other has mass 1.50 MeV/$c^2$ and momentum 2.00 MeV/$c$ in the positive $y$ direction. Find (a) the mass and (b) the speed of the original object.

77. The cosmic rays of highest energy are protons that have kinetic energy on the order of $10^{19}$ MeV. (a) As measured in the proton’s frame, what time interval would a proton of this energy require to travel across the Milky Way galaxy, which has a proper diameter $\sim 10^8$ light-years? (b) From the point of view of the proton, how many kilometers across is the galaxy?

78. Spacecraft I, containing students taking a physics exam, approaches the Earth with a speed of $0.600c$ (relative to the Earth), while spacecraft II, containing professors proctoring the exam, moves at $0.280c$ (relative to the Earth) directly toward the students. If the professors stop the exam after 50.0 min have passed on their clock, for what time interval does the exam last as measured by (a) the students and (b) an observer on the Earth?

79. Review. Around the core of a nuclear reactor shielded by a large pool of water, Cerenkov radiation appears as a blue glow. (See Fig. P17.38 on page 528.) Cerenkov radiation occurs when a particle travels faster through a medium than the speed of light in that medium. It is the electromagnetic equivalent of a bow wave or a sonic boom. An electron is traveling through water at a speed $10.0\%$ faster than the speed of light in water. Determine the electron’s (a) total energy, (b) kinetic energy, and (c) momentum. (d) Find the angle between the shock wave and the electron’s direction of motion.

80. The motion of a transparent medium influences the speed of light. This effect was first observed by Fizeau in 1851. Consider a light beam in water. The water moves with speed $v$ in a horizontal pipe. Assume the light travels in the same direction as the water moves. The speed of light with respect to the water is $c/n$, where $n = 1.33$ is the index of refraction of water. (a) Use the velocity transformation equation to show that the speed of the light measured in the laboratory frame is

$$u = \frac{c}{n \left(1 + nu/c^2\right)^{1/2}}$$

(b) Show that for $v << c$, the expression from part (a) becomes, to a good approximation,

$$u \approx \frac{c}{n} + v - \frac{v^2}{n^2}$$

(c) Argue for or against the view that we should expect the result to be $u = (c/n) + v$ according to the Galilean transformation and that the presence of the term $-v^2/n^2$ represents a relativistic effect appearing even at “nonrelativistic” speeds. (d) Evaluate $u$ in the limit as the speed of the water approaches $c$.

81. Imagine that the entire Sun, of mass $M_S$, collapses to a sphere of radius $R_g$ such that the work required to remove a small mass $m$ from the surface would be equal to its rest energy $mc^2$. This radius is called the gravitational radius for the Sun. (a) Use this approach to show that $R_g = GM_S/c^2$. (b) Find a numerical value for $R_g$.

82. Why is the following situation impossible? An experimenter is accelerating electrons for use in probing a material. She finds that when she accelerates them through a potential difference of 84.0 kV, the electrons have half the speed she wishes. She quadruples the potential difference to 336 kV, and the electrons accelerated through this potential difference have her desired speed.

83. An alien spaceship traveling at $0.600c$ toward the Earth launches a landing craft. The landing craft travels in the same direction with a speed of $0.800c$ relative to the mother ship. As measured on the Earth, the spaceship is 0.200 ly from the Earth when the landing craft is launched. (a) What speed do the Earth-based observers measure for the approaching landing craft? (b) What is the distance to the Earth at the moment of the landing craft’s launch as measured by the aliens? (c) What travel time is required for the landing craft to reach the Earth as measured by the aliens on the mother ship? (d) If the landing craft has a mass of $4.00 \times 10^8$ kg, what is its kinetic energy as measured in the Earth reference frame?

84. (a) Prepare a graph of the relativistic kinetic energy and the classical kinetic energy, both as a function of speed, for an object with a mass of your choice. (b) At what speed does the classical kinetic energy underestimate the experimental value by 1%? (c) By 5%? (d) By 50%?

85. An observer in a coasting spacecraft moves toward a mirror at speed $v = 0.650c$ relative to the reference frame labeled S in Figure P39.85 (page 1232). The mirror is stationary with respect to S. A light pulse emitted by the spacecraft travels toward the mirror and is
reflected back to the spacecraft. The spacecraft is a distance \( d = 5.66 \times 10^{10} \text{ m} \) from the mirror (as measured by observers in \( S \)) at the moment the light pulse leaves the spacecraft. What is the total travel time of the pulse as measured by observers in (a) the \( S \) frame and (b) the spacecraft?

![Figure P39.85](image)

**Figure P39.85** Problems 85 and 86.

86. An observer in a coasting spacecraft moves toward a mirror at speed \( v \) relative to the reference frame labeled \( S \) in Figure P39.85. The mirror is stationary with respect to \( S \). A light pulse emitted by the spacecraft travels toward the mirror and is reflected back to the spacecraft. The spacecraft is a distance \( d \) from the mirror (as measured by observers in \( S \)) at the moment the light pulse leaves the spacecraft. What is the total travel time of the pulse as measured by observers in (a) the \( S \) frame and (b) the spacecraft?

87. A \(^{57}\text{Fe} \) nucleus at rest emits a 14.0-keV photon. Use conservation of energy and momentum to find the kinetic energy of the recoiling nucleus in electron volts. Use \( Mc^2 = 8.60 \times 10^{-9} \text{ J} \) for the final state of the \(^{57}\text{Fe} \) nucleus.

**Challenge Problems**

88. A particle with electric charge \( q \) moves along a straight line in a uniform electric field \( \mathbf{E} \) with speed \( u \). The electric force exerted on the charge is \( q\mathbf{E} \). The velocity of the particle and the electric field are both in the \( x \) direction. (a) Show that the acceleration of the particle in the \( x \) direction is given by

\[
\alpha = \frac{du}{dt} = \frac{qE}{m} \left( 1 - \frac{v^2}{c^2} \right)^{3/2}
\]

(b) Discuss the significance of the dependence of the acceleration on the speed. (c) What If? If the particle starts from rest at \( x = 0 \) at \( t = 0 \), how would you proceed to find the speed of the particle and its position at time \( t \)?

89. The creation and study of new and very massive elementary particles is an important part of contemporary physics. To create a particle of mass \( M \) requires an energy \( Mc^2 \). With enough energy, an exotic particle can be created by allowing a fast-moving proton to collide with a similar target particle. Consider a perfectly inelastic collision between two protons: an incident proton with mass \( m_p \), kinetic energy \( K \), and momentum magnitude \( p \) joins with an originally stationary target proton to form a single product particle of mass \( M \). Not all the kinetic energy of the incoming proton is available to create the product particle because conservation of momentum requires that the system as a whole still must have some kinetic energy after the collision. Therefore, only a fraction of the energy of the incident particle is available to create a new particle. (a) Show that the energy available to create a product particle is given by

\[
Mc^2 = 2m_p c^2 \sqrt{1 + \frac{K}{2m_p c^2}}
\]

This result shows that when the kinetic energy \( K \) of the incident proton is large compared with its rest energy \( m_p c^2 \), then \( M \) approaches \((2m_p K)^{1/2}/c \). Therefore, if the energy of the incoming proton is increased by a factor of 9, the mass you can create increases only by a factor of 3, not by a factor of 9 as would be expected. (b) This problem can be alleviated by using **colliding beams** as is the case in most modern accelerators. Here the total momentum of a pair of interacting particles can be zero. The center of mass can be at rest after the collision, so, in principle, all the initial kinetic energy can be used for particle creation. Show that

\[
Mc^2 = 2mc^2 \left( 1 + \frac{K}{mc^2} \right)
\]

where \( K \) is the kinetic energy of each of the two identical colliding particles. Here, if \( K \gg mc^2 \), we have \( M \) directly proportional to \( K \) as we would desire.

90. Suppose our Sun is about to explode. In an effort to escape, we depart in a spacecraft at \( v = 0.800c \) and head toward the star Tau Ceti, 12.0 ly away. When we reach the midpoint of our journey from the Earth, we see our Sun explode, and, unfortunately, at the same instant, we see Tau Ceti explode as well. (a) In the spacecraft’s frame of reference, should we conclude that the two explosions occurred simultaneously? If not, which occurred first? (b) What If? In a frame of reference in which the Sun and Tau Ceti are at rest, did they explode simultaneously? If not, which exploded first?

91. Owen and Dina are at rest in frame \( S' \), which is moving at 0.600\(c \) with respect to frame \( S \). They play a game of catch while Ed, at rest in frame \( S \), watches the action (Fig. P39.91). Owen throws the ball to Dina at 0.800\(c \) (according to Owen), and their separation (measured in \( S' \)) is equal to 1.80 \(\times\) 10\(^{12}\) m. (a) According to Dina, how fast is the ball moving? (b) According to Dina, what time interval is required for the ball to reach her? According to Ed, (c) how far apart are Owen and Dina, (d) how fast is the ball moving, and (e) what time interval is required for the ball to reach Dina?

![Figure P39.91](image)
In Chapter 39, we discussed that Newtonian mechanics must be replaced by Einstein’s special theory of relativity when dealing with particle speeds comparable to the speed of light. As the 20th century progressed, many experimental and theoretical problems were resolved by the special theory of relativity. For many other problems, however, neither relativity nor classical physics could provide a theoretical answer. Attempts to apply the laws of classical physics to explain the behavior of matter on the atomic scale were consistently unsuccessful. For example, the emission of discrete wavelengths of light from atoms in a high-temperature gas could not be explained within the framework of classical physics.

As physicists sought new ways to solve these puzzles, another revolution took place in physics between 1900 and 1930. A new theory called quantum mechanics was highly successful in explaining the behavior of particles of microscopic size. Like the special theory of relativity, the quantum theory requires a modification of our ideas concerning the physical world.

The first explanation of a phenomenon using quantum theory was introduced by Max Planck. Many subsequent mathematical developments and interpretations were made by a number of distinguished physicists, including Einstein, Bohr, de Broglie, Schrödinger, and
Heisenberg. Despite the great success of the quantum theory, Einstein frequently played the role of its critic, especially with regard to the manner in which the theory was interpreted. Because an extensive study of quantum theory is beyond the scope of this book, this chapter is simply an introduction to its underlying principles.

### 40.1 Blackbody Radiation and Planck’s Hypothesis

An object at any temperature emits electromagnetic waves in the form of thermal radiation from its surface as discussed in Section 20.7. The characteristics of this radiation depend on the temperature and properties of the object’s surface. Careful study shows that the radiation consists of a continuous distribution of wavelengths from all portions of the electromagnetic spectrum. If the object is at room temperature, the wavelengths of thermal radiation are mainly in the infrared region and hence the radiation is not detected by the human eye. As the surface temperature of the object increases, the object eventually begins to glow visibly red, like the coils of a toaster. At sufficiently high temperatures, the glowing object appears white, as in the hot tungsten filament of an incandescent lightbulb.

From a classical viewpoint, thermal radiation originates from accelerated charged particles in the atoms near the surface of the object; those charged particles emit radiation much as small antennas do. The thermally agitated particles can have a distribution of energies, which accounts for the continuous spectrum of radiation emitted by the object. By the end of the 19th century, however, it became apparent that the classical theory of thermal radiation was inadequate. The basic problem was in understanding the observed distribution of wavelengths in the radiation emitted by a black body. As defined in Section 20.7, a black body is an ideal system that absorbs all radiation incident on it. The electromagnetic radiation emitted by the black body is called blackbody radiation.

A good approximation of a black body is a small hole leading to the inside of a hollow object as shown in Figure 40.1. Any radiation incident on the hole from outside the cavity enters the hole and is reflected a number of times on the interior walls of the cavity; hence, the hole acts as a perfect absorber. The nature of the radiation leaving the cavity through the hole depends only on the temperature of the cavity walls and not on the material of which the walls are made. The spaces between lumps of hot charcoal (Fig. 40.2) emit light that is very much like blackbody radiation.

The radiation emitted by oscillators in the cavity walls in Figure 40.1 experiences boundary conditions and can be analyzed using the waves under boundary conditions analysis model. As the radiation reflects from the cavity’s walls, standing electromagnetic waves are established within the three-dimensional interior of the cavity. Many standing-wave modes are possible, and the distribution of the energy in the cavity among these modes determines the wavelength distribution of the radiation leaving the cavity through the hole.

The wavelength distribution of radiation from cavities was studied experimentally in the late 19th century. Figure 40.5 shows how the intensity of blackbody radiation varies with temperature and wavelength. The following two consistent experimental findings were seen as especially significant:

1. **The total power of the emitted radiation increases with temperature.**
   We discussed this behavior briefly in Chapter 20, where we introduced Stefan’s law:

   \[
   P = \sigma A e T^4
   \]  

   where \( P \) is the power in watts radiated at all wavelengths from the surface of an object, \( \sigma = 5.670 \times 10^{-8} \text{ W/m}^2 \text{°K}^4 \) is the Stefan–Boltzmann constant, \( A \) is the surface area of the object in square meters, \( e \) is the emissivity of the
surface, and \( T \) is the surface temperature in kelvins. For a black body, the emissivity is \( \varepsilon = 1 \) exactly.

2. **The peak of the wavelength distribution shifts to shorter wavelengths as the temperature increases.** This behavior is described by the following relationship, called **Wien’s displacement law**:

\[
\lambda_{\text{max}} T = 2.898 \times 10^{-3} \text{ m} \cdot \text{K}
\]  

(40.2)

where \( \lambda_{\text{max}} \) is the wavelength at which the curve peaks and \( T \) is the absolute temperature of the surface of the object emitting the radiation. The wavelength at the curve’s peak is inversely proportional to the absolute temperature; that is, as the temperature increases, the peak is “displaced” to shorter wavelengths (Fig. 40.3).

Wien’s displacement law is consistent with the behavior of the object mentioned at the beginning of this section. At room temperature, the object does not appear to glow because the peak is in the infrared region of the electromagnetic spectrum. At higher temperatures, it glows red because the peak is in the near infrared with some radiation at the red end of the visible spectrum, and at still higher temperatures, it glows white because the peak is in the visible so that all colors are emitted.

**Quick Quiz 40.1** Figure 40.4 shows two stars in the constellation Orion. Betelgeuse appears to glow red, whereas Rigel looks blue in color. Which star has a higher surface temperature? (a) Betelgeuse (b) Rigel (c) both the same (d) impossible to determine

A successful theory for blackbody radiation must predict the shape of the curves in Figure 40.3, the temperature dependence expressed in Stefan’s law, and the shift of the peak with temperature described by Wien’s displacement law. Early attempts to use classical ideas to explain the shapes of the curves in Figure 40.3 failed.

Let’s consider one of these early attempts. To describe the distribution of energy from a black body, we define \( I(\lambda, T) \ d\lambda \) to be the intensity, or power per unit area, emitted in the wavelength interval \( \lambda \ d\lambda \). The result of a calculation based on a classical theory of blackbody radiation known as the **Rayleigh-Jeans law** is

\[
I(\lambda, T) = \frac{2\pi c k_B T}{\lambda^4}
\]

(40.3)

where \( k_B \) is Boltzmann’s constant. The black body is modeled as the hole leading into a cavity (Fig. 40.1), resulting in many modes of oscillation of the electromagnetic field caused by accelerated charges in the cavity walls and the emission of electromagnetic waves at all wavelengths. In the classical theory used to derive...
Equation 40.3, the average energy for each wavelength of the standing-wave modes is assumed to be proportional to $k_B T$, based on the theorem of equipartition of energy discussed in Section 21.1.

An experimental plot of the blackbody radiation spectrum, together with the theoretical prediction of the Rayleigh–Jeans law, is shown in Figure 40.5. At long wavelengths, the Rayleigh–Jeans law is in reasonable agreement with experimental data, but at short wavelengths, major disagreement is apparent.

As $\lambda$ approaches zero, the function $I(\lambda,T)$ given by Equation 40.3 approaches infinity. Hence, according to classical theory, not only should short wavelengths predominate in a blackbody spectrum, but also the energy emitted by any black body should become infinite in the limit of zero wavelength. In contrast to this prediction, the experimental data plotted in Figure 40.5 show that as $\lambda$ approaches zero, $I(\lambda,T)$ also approaches zero. This mismatch of theory and experiment was so disconcerting that scientists called it the ultraviolet catastrophe. (This “catastrophe”—infinite energy—occurs as the wavelength approaches zero; the word ultraviolet was applied because ultraviolet wavelengths are short.)

In 1900, Max Planck developed a theory of blackbody radiation that leads to an equation for $I(\lambda,T)$ that is in complete agreement with experimental results at all wavelengths. In discussing this theory, we use the outline of properties of structural models introduced in Chapter 21:

1. **Physical components:**
   - Planck assumed the cavity radiation came from atomic oscillators in the cavity walls in Figure 40.1.

2. **Behavior of the components:**
   - (a) The energy of an oscillator can have only certain discrete values $E_n$:
     $$E_n = n hf$$ (40.4)
     where $n$ is a positive integer called a quantum number, $f$ is the oscillator’s frequency, and $h$ is a parameter Planck introduced that is now called Planck’s constant. Because the energy of each oscillator can have only discrete values given by Equation 40.4, we say the energy is quantized. Each discrete energy value corresponds to a different quantum state, represented by the quantum number $n$. When the oscillator is in the $n=1$ quantum state, its energy is $hf$; when it is in the $n=2$ quantum state, its energy is $2hf$; and so on.
   - (b) The oscillators emit or absorb energy when making a transition from one quantum state to another. The entire energy difference between the initial and final states in the transition is emitted or absorbed as a single quantum of radiation. If the transition is from one state to a lower adjacent state—say, from the $n=3$ state to the $n=2$ state—Equation 40.4 shows that the amount of energy emitted by the oscillator and carried by the quantum of radiation is
     $$E = hf$$ (40.5)

According to property 2(b), an oscillator emits or absorbs energy only when it changes quantum states. If it remains in one quantum state, no energy is absorbed or emitted. Figure 40.6 is an energy-level diagram showing the quantized energy levels and allowed transitions proposed by Planck. This important semigraphical representation is used often in quantum physics. The vertical axis is linear in energy, and the allowed energy levels are represented as horizontal lines. The quantized system can have only the energies represented by the horizontal lines.
The key point in Planck’s theory is the radical assumption of quantized energy states. This development—a clear deviation from classical physics—marked the birth of the quantum theory.

In the Rayleigh–Jeans model, the average energy associated with a particular wavelength of standing waves in the cavity is the same for all wavelengths and is equal to \( k_B T \). Planck used the same classical ideas as in the Rayleigh–Jeans model to arrive at the energy density as a product of constants and the average energy for a given wavelength, but the average energy is not given by the equipartition theorem. A wave’s average energy is the average energy difference between levels of the oscillator, weighted according to the probability of the wave being emitted. This weighting is based on the occupation of higher-energy states as described by the Boltzmann distribution law, which was discussed in Section 21.5. According to this law, the probability of a state being occupied is proportional to the factor \( e^{-E/k_B T} \), where \( E \) is the energy of the state.

At low frequencies (long wavelengths), according to property 2(a), the energy levels are close together as on the right in Figure 40.7, and many of the energy states are excited because the Boltzmann factor \( e^{-E/k_B T} \) is relatively large for these states. Therefore, there are many contributions to the outgoing radiation, although each contribution has very low energy. Now, consider high-frequency radiation, that is, radiation with short wavelength. To obtain this radiation, the allowed energies are very far apart as on the left in Figure 40.7. The probability of thermal agitation exciting these high energy levels is small because of the small value of the Boltzmann factor for large values of \( E \). At high frequencies, the low probability of excitation results in very little contribution to the total energy, even though each quantum is of large energy. This low probability “turns the curve over” and brings it down to zero again at short wavelengths.

Using this approach, Planck generated a theoretical expression for the wavelength distribution that agreed remarkably well with the experimental curves in Figure 40.3:

\[
I(\lambda, T) = \frac{2\pi \hbar^2}{\lambda^5} \frac{e^{\hbar c / \lambda k_B T} - 1}{e^{\hbar c / \lambda k_B T}}
\]

(40.6)
This function includes the parameter $h$, which Planck adjusted so that his curve matched the experimental data at all wavelengths. The value of this parameter is found to be independent of the material of which the black body is made and independent of the temperature; it is a fundamental constant of nature. The value of $h$, Planck’s constant, which was first introduced in Chapter 35, is

$$h = 6.626 \times 10^{-34} \text{ J} \cdot \text{s} \quad (40.7)$$

At long wavelengths, Equation 40.6 reduces to the Rayleigh–Jeans expression, Equation 40.3 (see Problem 14), and at short wavelengths, it predicts an exponential decrease in $I(\lambda,T)$ with decreasing wavelength, in agreement with experimental results.

When Planck presented his theory, most scientists (including Planck!) did not consider the quantum concept to be realistic. They believed it was a mathematical trick that happened to predict the correct results. Hence, Planck and others continued to search for a more “rational” explanation of blackbody radiation. Subsequent developments, however, showed that a theory based on the quantum concept (rather than on classical concepts) had to be used to explain not only blackbody radiation but also a number of other phenomena at the atomic level.

In 1905, Einstein rederived Planck’s results by assuming the oscillations of the electromagnetic field were themselves quantized. In other words, he proposed that quantization is a fundamental property of light and other electromagnetic radiation, which led to the concept of photons as shall be discussed in Section 40.2. Critical to the success of the quantum or photon theory was the relation between energy and frequency, which classical theory completely failed to predict.

You may have had your body temperature measured at the doctor’s office by an *ear thermometer*, which can read your temperature very quickly (Fig. 40.8). In a fraction of a second, this type of thermometer measures the amount of infrared radiation emitted by the eardrum. It then converts the amount of radiation into a temperature reading. This thermometer is very sensitive because temperature is raised to the fourth power in Stefan’s law. Suppose you have a fever 1°C above normal. Because absolute temperatures are found by adding 273 to Celsius temperatures, the ratio of your fever temperature to normal body temperature of 37°C is

$$\frac{T_{\text{fever}}}{T_{\text{normal}}} = \frac{38^\circ \text{C} + 273^\circ \text{C}}{37^\circ \text{C} + 273^\circ \text{C}} = 1.0032$$

which is only a 0.32% increase in temperature. The increase in radiated power, however, is proportional to the fourth power of temperature, so

$$\frac{P_{\text{fever}}}{P_{\text{normal}}} = \left(\frac{38^\circ \text{C} + 273^\circ \text{C}}{37^\circ \text{C} + 273^\circ \text{C}}\right)^4 = 1.013$$

The result is a 1.3% increase in radiated power, which is easily measured by modern infrared radiation sensors.

**Example 40.1**  **Thermal Radiation from Different Objects**

**(A)** Find the peak wavelength of the blackbody radiation emitted by the human body when the skin temperature is 35°C.

**Solution**

**Conceptualize** Thermal radiation is emitted from the surface of any object. The peak wavelength is related to the surface temperature through Wien’s displacement law (Eq. 40.2).

**Categorize** We evaluate results using an equation developed in this section, so we categorize this example as a substitution problem.
Solve Equation 40.2 for $\lambda_{\text{max}}$:

$$\lambda_{\text{max}} = \frac{2.898 \times 10^{-3} \text{ m} \cdot \text{K}}{T}$$  \hspace{1cm} (1)

Substitute the surface temperature:

$$\lambda_{\text{max}} = \frac{2.898 \times 10^{-3} \text{ m} \cdot \text{K}}{308 \text{ K}} = 9.41 \text{ \mu m}$$

This radiation is in the infrared region of the spectrum and is invisible to the human eye. Some animals (pit vipers, for instance) are able to detect radiation of this wavelength and therefore can locate warm-blooded prey even in the dark.

(C) Find the peak wavelength of the blackbody radiation emitted by the Sun, which has a surface temperature of approximately 5,800 K.

**Solution**

Substitute the surface temperature into Equation (1):

$$\lambda_{\text{max}} = \frac{2.898 \times 10^{-3} \text{ m} \cdot \text{K}}{5,800 \text{ K}} = 0.500 \text{ \mu m}$$

This radiation is near the center of the visible spectrum, near the color of a yellow-green tennis ball. Because it is the most prevalent color in sunlight, our eyes have evolved to be most sensitive to light of approximately this wavelength.

---

**Example 40.2**  The Quantized Oscillator  AM

A 2.00-kg block is attached to a massless spring that has a force constant of $k = 25.0 \text{ N/m}$. The spring is stretched 0.400 m from its equilibrium position and released from rest.

(A) Find the total energy of the system and the frequency of oscillation according to classical calculations.

**Solution**

Conceptualize  We understand the details of the block’s motion from our study of simple harmonic motion in Chapter 15. Review that material if you need to.

Categorize  The phrase “according to classical calculations” tells us to categorize this part of the problem as a classical analysis of the oscillator. We model the block as a *particle in simple harmonic motion*.

Analyze  Based on the way the block is set into motion, its amplitude is 0.400 m.

Evaluate the total energy of the block–spring system using Equation 15.21:

$$E = \frac{1}{2}kA^2 = \frac{1}{2}(25.0 \text{ N/m})(0.400 \text{ m})^2 = 2.00 \text{ J}$$

Evaluate the frequency of oscillation from Equation 15.14:

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{m}} = \frac{1}{2\pi} \sqrt{\frac{25.0 \text{ N/m}}{2.00 \text{ kg}}} = 0.563 \text{ Hz}$$

(B) Assuming the energy of the oscillator is quantized, find the quantum number $n$ for the system oscillating with this amplitude.

*continued*
40.2 The Photoelectric Effect

Blackbody radiation was the first phenomenon to be explained with a quantum model. In the latter part of the 19th century, at the same time that data were taken on thermal radiation, experiments showed that light incident on certain metallic surfaces causes electrons to be emitted from those surfaces. This phenomenon, which was first discussed in Section 35.1, is known as the photoelectric effect, and the emitted electrons are called photoelectrons. 3

Figure 40.9 is a diagram of an apparatus for studying the photoelectric effect. An evacuated glass or quartz tube contains a metallic plate E (the emitter) connected to the negative terminal of a battery and another metallic plate C (the collector) that is connected to the positive terminal of the battery. When the tube is kept in the dark, the ammeter reads zero, indicating no current in the circuit. However, when plate E is illuminated by light having an appropriate wavelength, a current is detected by the ammeter, indicating a flow of charges across the gap between plates E and C. This current arises from photoelectrons emitted from plate E and collected at plate C.

Figure 40.10 is a plot of photoelectric current versus potential difference ΔV applied between plates E and C for two light intensities. At large values of ΔV, the current reaches a maximum value; all the electrons emitted from E are collected at C, and the current cannot increase further. In addition, the maximum current increases as the intensity of the incident light increases, as you might expect.

3Photoelectrons are not different from other electrons. They are given this name solely because of their ejection from a metal by light in the photoelectric effect.
because more electrons are ejected by the higher-intensity light. Finally, when $\Delta V$ is negative—that is, when the battery in the circuit is reversed to make plate E positive and plate C negative—the current drops because many of the photoelectrons emitted from E are repelled by the now negative plate C. In this situation, only those photoelectrons having a kinetic energy greater than $e|\Delta V|$ reach plate C, where $e$ is the magnitude of the charge on the electron. When $\Delta V$ is equal to or more negative than $-\Delta V_i$, where $\Delta V_i$ is the stopping potential, no photoelectrons reach C and the current is zero.

Let’s model the combination of the electric field between the plates and an electron ejected from plate E as an isolated system. Suppose this electron stops just as it reaches plate C. Because the system is isolated, the appropriate reduction of Equation 8.2 is

$$\Delta K + \Delta U = 0$$

where the initial configuration is at the instant the electron leaves the metal with kinetic energy $K_i$ and the final configuration is when the electron stops just before touching plate C. If we define the electric potential energy of the system in the initial configuration to be zero, we have

$$(0 - K_i) + [(q)(\Delta V) - 0] = 0 \quad \rightarrow \quad K_f = q\Delta V = -e\Delta V$$

Now suppose the potential difference $\Delta V$ is increased in the negative direction just until the current is zero at $\Delta V = -\Delta V_i$. In this case, the electron that stops immediately before reaching plate C has the maximum possible kinetic energy upon leaving the metal surface. The previous equation can then be written as

$$K_{\text{max}} = e\Delta V_i \quad \text{(40.8)}$$

This equation allows us to measure $K_{\text{max}}$ experimentally by determining the magnitude of the voltage $\Delta V_i$ at which the current drops to zero.

Several features of the photoelectric effect are listed below. For each feature, we compare the predictions made by a classical approach, using the wave model for light, with the experimental results.

1. Dependence of photoelectron kinetic energy on light intensity

*Classical prediction:* Electrons should absorb energy continuously from the electromagnetic waves. As the light intensity incident on a metal is increased, energy should be transferred into the metal at a higher rate and the electrons should be ejected with more kinetic energy.

*Experimental result:* The maximum kinetic energy of photoelectrons is independent of light intensity as shown in Figure 40.10 with both curves falling to zero at the same negative voltage. (According to Equation 40.8, the maximum kinetic energy is proportional to the stopping potential.)
2. Time interval between incidence of light and ejection of photoelectrons

*Classical prediction:* At low light intensities, a measurable time interval should pass between the instant the light is turned on and the time an electron is ejected from the metal. This time interval is required for the electron to absorb the incident radiation before it acquires enough energy to escape from the metal.

*Experimental result:* Electrons are emitted from the surface of the metal almost *instantaneously* (less than $10^{-9}$ s after the surface is illuminated), even at very low light intensities.

3. Dependence of ejection of electrons on light frequency

*Classical prediction:* Electrons should be ejected from the metal at any incident light frequency, as long as the light intensity is high enough, because energy is transferred to the metal regardless of the incident light frequency.

*Experimental result:* No electrons are emitted if the incident light frequency falls below some *cutoff frequency* $f_c$, whose value is characteristic of the material being illuminated. No electrons are ejected below this cutoff frequency *regardless* of the light intensity.

4. Dependence of photoelectron kinetic energy on light frequency

*Classical prediction:* There should be no relationship between the frequency of the light and the electron kinetic energy. The kinetic energy should be related to the intensity of the light.

*Experimental result:* The maximum kinetic energy of the photoelectrons increases with increasing light frequency.

For these features, experimental results contradict *all four* classical predictions. A successful explanation of the photoelectric effect was given by Einstein in 1905, the same year he published his special theory of relativity. As part of a general paper on electromagnetic radiation, for which he received a Nobel Prize in Physics in 1921, Einstein extended Planck’s concept of quantization to electromagnetic waves as mentioned in Section 40.1. Einstein assumed light (or any other electromagnetic wave) of frequency $f$ from *any* source can be considered a stream of quanta. Today we call these quanta **photons**. Each photon has an energy $E$ given by Equation 40.5, $E = hf$, and each moves in a vacuum at the speed of light $c$, where $c = 3.00 \times 10^8$ m/s.

**Quick Quiz 40.2** While standing outdoors one evening, you are exposed to the following four types of electromagnetic radiation: yellow light from a sodium street lamp, radio waves from an AM radio station, radio waves from an FM radio station, and microwaves from an antenna of a communications system.

- Rank these types of waves in terms of photon energy from highest to lowest.

Let us organize Einstein’s model for the photoelectric effect using the properties of structural models:

1. **Physical components:**
   - We imagine the system to consist of two physical components: (1) an electron that is to be ejected by an incoming photon and (2) the remainder of the metal.

2. **Behavior of the components:**
   - (a) In Einstein’s model, a photon of the incident light gives *all* its energy $hf$ to a *single* electron in the metal. Therefore, the absorption of energy by the electrons is not a continuous process as envisioned in the wave model, but rather a discontinuous process in which energy is delivered to the electrons in bundles. The energy transfer is accomplished via a one-photon/one-electron event.\(^{4}\)

\(^{4}\)In principle, two photons could combine to provide an electron with their combined energy. That is highly improbable, however, without the high intensity of radiation available from very strong lasers.
(b) We can describe the time evolution of the system by applying the non-isolated system model for energy over a time interval that includes the absorption of one photon and the ejection of the corresponding electron. Energy is transferred into the system by electromagnetic radiation, the photon. The system has two types of energy: the potential energy of the metal–electron system and the kinetic energy of the ejected electron. Therefore, we can write the conservation of energy equation (Eq. 8.2) as

$$\Delta K + \Delta U = T_{ER}$$  \hspace{1cm} (40.9)

The energy transfer into the system is that of the photon, $T_{ER} = hf$. During the process, the kinetic energy of the electron increases from zero to its final value, which we assume to be the maximum possible value $K_{\text{max}}$. The potential energy of the system increases because the electron is pulled away from the metal to which it is attracted. We define the potential energy of the system when the electron is outside the metal as zero. The potential energy of the system when the electron is in the metal is $U = -\phi$, where $\phi$ is called the work function of the metal. The work function represents the minimum energy with which an electron is bound in the metal and is on the order of a few electron volts. Table 40.1 lists selected values. The increase in potential energy of the system when the electron is removed from the metal is the work function $\phi$. Substituting these energies into Equation 40.9, we have

$$(K_{\text{max}} - 0) + [0 - (-\phi)] = hf$$

$$K_{\text{max}} + \phi = hf$$  \hspace{1cm} (40.10)

If the electron makes collisions with other electrons or metal ions as it is being ejected, some of the incoming energy is transferred to the metal and the electron is ejected with less kinetic energy than $K_{\text{max}}$.

The prediction made by Einstein is an equation for the maximum kinetic energy of an ejected electron as a function of frequency of the illuminating radiation. This equation can be found by rearranging Equation 40.10:

$$K_{\text{max}} = hf - \phi$$  \hspace{1cm} (40.11)

With Einstein’s structural model, one can explain the observed features of the photoelectric effect that cannot be understood using classical concepts:

1. **Dependence of photoelectron kinetic energy on light intensity**
   
   Equation 40.11 shows that $K_{\text{max}}$ is independent of the light intensity. The maximum kinetic energy of any one electron, which equals $hf - \phi$, depends only on the light frequency and the work function. If the light intensity is doubled, the number of photons arriving per unit time is doubled, which doubles the rate at which photoelectrons are emitted. The maximum kinetic energy of any one photoelectron, however, is unchanged.

2. **Time interval between incidence of light and ejection of photoelectrons**
   
   Near-instantaneous emission of electrons is consistent with the photon model of light. The incident energy appears in small packets, and there is a one-to-one interaction between photons and electrons. If the incident light has very low intensity, there are very few photons arriving per unit time interval; each photon, however, can have sufficient energy to eject an electron immediately.

3. **Dependence of ejection of electrons on light frequency**
   
   Because the photon must have energy greater than the work function $\phi$ to eject an electron, the photoelectric effect cannot be observed below a

Note: Values are typical for metals listed. Actual values may vary depending on whether the metal is a single crystal or polycrystalline. Values may also depend on the face from which electrons are ejected from crystalline metals. Furthermore, different experimental procedures may produce differing values.
certain cutoff frequency. If the energy of an incoming photon does not satisfy this requirement, an electron cannot be ejected from the surface, even though many photons per unit time are incident on the metal in a very intense light beam.

4. Dependence of photoelectron kinetic energy on light frequency

A photon of higher frequency carries more energy and therefore ejects a photoelectron with more kinetic energy than does a photon of lower frequency.

Einstein’s model predicts a linear relationship (Eq. 40.11) between the maximum electron kinetic energy $K_{\text{max}}$ and the light frequency $f$. Experimental observation of a linear relationship between $K_{\text{max}}$ and $f$ would be a final confirmation of Einstein’s theory. Indeed, such a linear relationship was observed experimentally within a few years of Einstein’s theory and is sketched in Figure 40.11. The slope of the lines in such a plot is Planck’s constant $h$. The intercept on the horizontal axis gives the cutoff frequency below which no photoelectrons are emitted. The cutoff frequency is related to the work function through the relationship $f_c = \phi / h$. The cutoff frequency corresponds to a cutoff wavelength $\lambda_c$, where

$$\lambda_c = \frac{c}{f_c} = \frac{c}{\phi / h} = \frac{hc}{\phi} \quad (40.12)$$

and $c$ is the speed of light. Wavelengths greater than $\lambda_c$ incident on a material having a work function $\phi$ do not result in the emission of photoelectrons.

The combination $hc$ in Equation 40.12 often occurs when relating a photon’s energy to its wavelength. A common shortcut when solving problems is to express this combination in useful units according to the following approximation:

$$hc = 1.24 \text{ eV} \cdot \text{nm}$$

One of the first practical uses of the photoelectric effect was as the detector in a camera’s light meter. Light reflected from the object to be photographed strikes a photoelectric surface in the meter, causing it to emit photoelectrons that then pass through a sensitive ammeter. The magnitude of the current in the ammeter depends on the light intensity.

The phototube, another early application of the photoelectric effect, acts much like a switch in an electric circuit. It produces a current in the circuit when light of sufficiently high frequency falls on a metal plate in the phototube, but produces no current in the dark. Phototubes were used in burglar alarms and in the detection of the soundtrack on motion picture film. Modern semiconductor devices have now replaced older devices based on the photoelectric effect.
Today, the photoelectric effect is used in the operation of photomultiplier tubes. Figure 40.12 shows the structure of such a device. A photon striking the photocathode ejects an electron by means of the photoelectric effect. This electron accelerates across the potential difference between the photocathode and the first dynode, shown as being at +200 V relative to the photocathode in Figure 40.12. This high-energy electron strikes the dynode and ejects several more electrons. The same process is repeated through a series of dynodes at ever higher potentials until an electrical pulse is produced as millions of electrons strike the last dynode. The tube is therefore called a multiplier: one photon at the input has resulted in millions of electrons at the output.

The photomultiplier tube is used in nuclear detectors to detect photons produced by the interaction of energetic charged particles or gamma rays with certain materials. It is also used in astronomy in a technique called photometric photometry. In that technique, the light collected by a telescope from a single star is allowed to fall on a photomultiplier tube for a time interval. The tube measures the total energy transferred by light during the time interval, which can then be converted to a luminosity of the star.

The photomultiplier tube is being replaced in many astronomical observations with a charge-coupled device (CCD), which is the same device used in a digital camera (Section 36.6). Half of the 2009 Nobel Prize in Physics was awarded to Willard S. Boyle (b. 1924) and George E. Smith (b. 1930) for their 1969 invention of the charge-coupled device. In a CCD, an array of pixels is formed on the silicon surface of an integrated circuit (Section 43.7). When the surface is exposed to light from an astronomical scene through a telescope or a terrestrial scene through a digital camera, electrons generated by the photoelectric effect are caught in "traps" beneath the surface. The number of electrons is related to the intensity of the light striking the surface. A signal processor measures the number of electrons associated with each pixel and converts this information into a digital code that a computer can use to reconstruct and display the scene.

The electron bombardment CCD camera allows higher sensitivity than a conventional CCD. In this device, electrons ejected from a photocathode by the photoelectric effect are accelerated through a high voltage before striking a CCD array. The higher energy of the electrons results in a very sensitive detector of low-intensity radiation.

Quick Quiz 40.3 Consider one of the curves in Figure 40.10. Suppose the intensity of the incident light is held fixed but its frequency is increased. Does the stopping potential in Figure 40.10 (a) remain fixed, (b) move to the right, or (c) move to the left?

Quick Quiz 40.4 Suppose classical physicists had the idea of plotting $K_{\text{max}}$ versus $f$ as in Figure 40.11. Draw a graph of what the expected plot would look like, based on the wave model for light.
40.3 The Compton Effect

In 1919, Einstein concluded that a photon of energy $E$ travels in a single direction and carries a momentum equal to $E/c$. In 1923, Arthur Holly Compton (1892–1962) and Peter Debye (1884–1966) independently carried Einstein’s idea of photon momentum further.

Prior to 1922, Compton and his coworkers had accumulated evidence showing that the classical wave theory of light failed to explain the scattering of x-rays from electrons. According to classical theory, electromagnetic waves of frequency $f$ incident on electrons should have two effects: (1) radiation pressure (see Section 34.5) should cause the electrons to accelerate in the direction of propagation of the waves, and (2) the oscillating electric field of the incident radiation should set the electrons into oscillation at the apparent frequency $f_\text{app}$, where $f_\text{app}$ is the frequency in the frame of the moving electrons. This apparent frequency is different from the frequency $f$ of the incident radiation because of the Doppler effect (see Section 17.4). Each electron first absorbs radiation as a moving particle and then reradiates as a moving particle, thereby exhibiting two Doppler shifts in the frequency of radiation.

Because different electrons move at different speeds after the interaction, depending on the amount of energy absorbed from the electromagnetic waves, the scattered wave frequency at a given angle to the incoming radiation should show a distribution of Doppler-shifted values. Contrary to this prediction, Compton’s experiments showed that at a given angle only one frequency of radiation is observed. Compton and his coworkers explained these experiments by treating photons not as waves but rather as point-like particles having energy $hf$ and momentum $hf/c$ and by assuming the energy and momentum of the isolated system of the colliding photon–electron pair are conserved. Compton adopted a particle model for something that was well known as a wave, and today this scattering phenomenon is known as the Compton effect.

Figure 40.13 shows the quantum picture of the collision between an individual x-ray photon of frequency $f_\text{0}$ and an electron. In the quantum model, the electron is scattered through an angle $\phi$ with respect to this direction as in a billiard-ball type of collision. (The symbol $\phi$ used here is an angle and is not to be confused with the work function, which was discussed in the preceding section.) Compare Figure 40.13 with the two-dimensional collision shown in Figure 9.11.

Figure 40.14 is a schematic diagram of the apparatus used by Compton. The x-rays, scattered from a carbon target, were diffracted by a rotating crystal spectrometer, and the intensity was measured with an ionization chamber that generated a current proportional to the intensity. The incident beam consisted of monochromatic x-rays of wavelength $\lambda_\text{0} = 0.071$ nm. The experimental intensity-
versus-wavelength plots observed by Compton for four scattering angles (corresponding to $\theta$ in Fig. 40.13) are shown in Figure 40.15. The graphs for the three nonzero angles show two peaks, one at $\lambda_0$ and one at $\lambda' > \lambda_0$. The shifted peak at $\lambda'$ is caused by the scattering of x-rays from free electrons, which was predicted by Compton to depend on scattering angle as

$$\lambda' - \lambda_0 = \frac{h}{m_e c} (1 - \cos \theta) \quad (40.13)$$

where $m_e$ is the mass of the electron. This expression is known as the Compton shift equation and correctly describes the positions of the peaks in Figure 40.15. The factor $h/m_e c$, called the Compton wavelength of the electron, has a currently accepted value of

$$\lambda_C = \frac{h}{m_e c} = 0.00243 \text{ nm}$$

The unshifted peak at $\lambda_0$ in Figure 40.15 is caused by x-rays scattered from electrons tightly bound to the target atoms. This unshifted peak also is predicted by Equation 40.13 if the electron mass is replaced with the mass of a carbon atom, which is approximately 23 000 times the mass of the electron. Therefore, there is a wavelength shift for scattering from an electron bound to an atom, but it is so small that it was undetectable in Compton’s experiment.

Compton’s measurements were in excellent agreement with the predictions of Equation 40.13. These results were the first to convince many physicists of the fundamental validity of quantum theory.

Quick Quiz 40.5 For any given scattering angle $\theta$, Equation 40.15 gives the same value for the Compton shift for any wavelength. Keeping that in mind, for which of the following types of radiation is the fractional shift in wavelength at a given scattering angle the largest? (a) radio waves (b) microwaves (c) visible light (d) x-rays

**Derivation of the Compton Shift Equation**

We can derive the Compton shift equation by assuming the photon behaves like a particle and collides elastically with a free electron initially at rest as shown in Figure 40.13. The photon is treated as a particle having energy $E = hf = hc/\lambda$ and zero rest energy. We apply the isolated system analysis models for energy and momentum to the photon and the electron. In the scattering process, the total energy and total linear momentum of the system are conserved. Applying the isolated system model for energy to this process gives

$$\Delta K_{\text{photon}} + \Delta K_e = 0 \rightarrow \frac{hc}{\lambda_0} = \frac{hc}{\lambda'} + K_e$$
where \( \frac{hc}{\lambda_0} \) is the energy of the incident photon, \( \frac{hc}{\lambda'} \) is the energy of the scattered photon, and \( K_e \) is the kinetic energy of the recoiling electron. Because the electron may recoil at a speed comparable to that of light, we must use the relativistic expression \( K_e = (\gamma - 1)m_ec^2 \) (Eq. 39.23). Therefore,

\[
\frac{hc}{\lambda_0} = \frac{hc}{\lambda'} + (\gamma - 1)m_ec^2 \tag{40.14}
\]

where \( \gamma = \frac{1}{\sqrt{1 - (u^2/c^2)}} \) and \( u \) is the speed of the electron.

Next, let’s apply the isolated system model for momentum to this collision, noting that the \( x \) and \( y \) components of momentum are each conserved independently. Equation 39.28 shows that the momentum of a photon has a magnitude \( p = \frac{E}{c} \), and we know from Equation 40.5 that \( E = hf \). Therefore, \( p = \frac{hf}{c} \). Substituting \( \lambda f \) for \( c \) (Eq. 34.20) in this expression gives \( p = \frac{h}{\lambda} \). Because the relativistic expression for the momentum of the recoiling electron is \( p_e = \gamma m_u \) (Eq. 39.19), we obtain

the following expressions for the \( x \) and \( y \) components of linear momentum, where

\[
x \text{ component: } \frac{h}{\lambda_0} \cos \theta + \gamma m_u \cos \phi \tag{40.15}
\]

\[
y \text{ component: } \frac{h}{\lambda'} \sin \theta - \gamma m_u \sin \phi \tag{40.16}
\]

Eliminating \( u \) and \( \phi \) from Equations 40.14 through 40.16 gives a single expression that relates the remaining three variables (\( \lambda', \lambda_0, \) and \( \theta \)). After some algebra (see Problem 64), we obtain Equation 40.13.

**Example 40.4**  **Compton Scattering at 45°**

X-rays of wavelength \( \lambda_0 = 0.200 \, 000 \, \text{nm} \) are scattered from a block of material. The scattered x-rays are observed at an angle of 45.0° to the incident beam. Calculate their wavelength.

**Solution**

**Conceptualize**  Imagine the process in Figure 40.13, with the photon scattered at 45° to its original direction.

**Categorize**  We evaluate the result using an equation developed in this section, so we categorize this example as a substitution problem.

Solve Equation 40.13 for the wavelength of the scattered x-ray:

\[(1) \quad \lambda' = \lambda_0 + \frac{h(1 - \cos \theta)}{m_ec} \]

Substitute numerical values:

\[
\lambda' = 0.200 \, 000 \times 10^{-9} \, \text{m} + \frac{(6.626 \times 10^{-34} \, \text{J} \cdot \text{s})(1 - \cos 45.0°)}{(9.11 \times 10^{-31} \, \text{kg})(3.00 \times 10^{8} \, \text{m/s})}
\]

\[
= 0.200 \, 000 \times 10^{-9} \, \text{m} + 7.10 \times 10^{-13} \, \text{m} = 0.200 \, 710 \, \text{nm}
\]

**What if?**  What if the detector is moved so that scattered x-rays are detected at an angle larger than 45°? Does the wavelength of the scattered x-rays increase or decrease as the angle \( \theta \) increases?

**Answer**  In Equation (1), if the angle \( \theta \) increases, \( \cos \theta \) decreases. Consequently, the factor \( (1 - \cos \theta) \) increases. Therefore, the scattered wavelength increases.

We could also apply an energy argument to achieve this same result. As the scattering angle increases, more energy is transferred from the incident photon to the electron. As a result, the energy of the scattered photon decreases with increasing scattering angle. Because \( E = hf \), the frequency of the scattered photon decreases, and because \( \lambda = c/f \), the wavelength increases.
40.4 The Nature of Electromagnetic Waves

In Section 35.1, we introduced the notion of competing models of light: particles and waves. Let’s expand on that earlier discussion. Phenomena such as the photoelectric effect and the Compton effect offer ironclad evidence that when light (or other forms of electromagnetic radiation) and matter interact, the light behaves as if it were composed of particles having energy $hf$ and momentum $h/\lambda$. How can light be considered a photon (in other words, a particle) when we know it is a wave? On the one hand, we describe light in terms of photons having energy and momentum. On the other hand, light and other electromagnetic waves exhibit interference and diffraction effects, which are consistent only with a wave interpretation.

Which model is correct? Is light a wave or a particle? The answer depends on the phenomenon being observed. Some experiments can be explained either better or solely with the photon model, whereas others are explained either better or solely with the wave model. We must accept both models and admit that the true nature of light is not describable in terms of any single classical picture. The same light beam that can eject photoelectrons from a metal (meaning that the beam consists of photons) can also be diffracted by a grating (meaning that the beam is a wave). In other words, the particle model and the wave model of light complement each other.

The success of the particle model of light in explaining the photoelectric effect and the Compton effect raises many other questions. If light is a particle, what is the meaning of the “frequency” and “wavelength” of the particle, and which of these two properties determines its energy and momentum? Is light simultaneously a wave and a particle? Although photons have no rest energy (a nonobservable quantity because a photon cannot be at rest), is there a simple expression for the effective mass of a moving photon? If photons have effective mass, do they experience gravitational attraction? What is the spatial extent of a photon, and how does an electron absorb or scatter one photon? Some of these questions can be answered, but others demand a view of atomic processes that is too pictorial and literal. Many of them stem from classical analogies such as colliding billiard balls and ocean waves breaking on a seashore. Quantum mechanics gives light a more flexible nature by treating the particle model and the wave model of light as both necessary and complementary. Neither model can be used exclusively to describe all properties of light. A complete understanding of the observed behavior of light can be attained only if the two models are combined in a complementary manner.

40.5 The Wave Properties of Particles

Students introduced to the dual nature of light often find the concept difficult to accept. In the world around us, we are accustomed to regarding such things as baseballs solely as particles and other things such as sound waves solely as forms of wave motion. Every large-scale observation can be interpreted by considering either a wave explanation or a particle explanation, but in the world of photons and electrons, such distinctions are not as sharply drawn.

Even more disconcerting is that, under certain conditions, the things we unambiguously call “particles” exhibit wave characteristics. In his 1923 doctoral dissertation, Louis de Broglie postulated that because photons have both wave and particle characteristics, perhaps all forms of matter have both properties. This highly revolutionary idea had no experimental confirmation at the time. According to de Broglie, electrons, just like light, have a dual particle–wave nature.

In Section 40.3, we found that the momentum of a photon can be expressed as

$$p = \frac{h}{\lambda}$$

Louis de Broglie
French Physicist (1892–1987)

De Broglie was born in Dieppe, France. At the Sorbonne in Paris, he studied history in preparation for what he hoped would be a career in the diplomatic service. The world of science is lucky he changed his career path to become a theoretical physicist. De Broglie was awarded the Nobel Prize in Physics in 1929 for his prediction of the wave nature of electrons.
This equation shows that the photon wavelength can be specified by its momentum: \( \lambda = \frac{h}{p} \). De Broglie suggested that material particles of momentum \( p \) have a characteristic wavelength that is given by the same expression. Because the magnitude of the momentum of a particle of mass \( m \) and speed \( u \) is \( p = mu \), the de Broglie wavelength of that particle is:

\[
\lambda = \frac{h}{p} = \frac{h}{mu}
\]  

(40.17)

Furthermore, in analogy with photons, de Broglie postulated that particles obey the Einstein relation \( E = hf \), where \( E \) is the total energy of the particle. The frequency of a particle is then:

\[
f = \frac{E}{h}
\]  

(40.18)

The dual nature of matter is apparent in Equations 40.17 and 40.18 because each contains both particle quantities (\( p \) and \( E \)) and wave quantities (\( \lambda \) and \( f \)).

The problem of understanding the dual nature of matter and radiation is conceptually difficult because the two models seem to contradict each other. This problem as it applies to light was discussed earlier. The principle of complementarity states that the wave and particle models of either matter or radiation complement each other.

Neither model can be used exclusively to describe matter or radiation adequately. Because humans tend to generate mental images based on their experiences from the everyday world, we use both descriptions in a complementary manner to explain any given set of data from the quantum world.

**The Davisson–Germer Experiment**

De Broglie’s 1923 proposal that matter exhibits both wave and particle properties was regarded as pure speculation. If particles such as electrons had wave properties, under the correct conditions they should exhibit diffraction effects. Only three years later, C. J. Davisson (1881–1958) and L. H. Germer (1896–1971) succeeded in observing electron diffraction and measuring the wavelength of electrons. Their important discovery provided the first experimental confirmation of the waves proposed by de Broglie.

Interestingly, the intent of the initial Davisson–Germer experiment was not to confirm the de Broglie hypothesis. In fact, their discovery was made by accident (as is often the case). The experiment involved the scattering of low-energy electrons (approximately 54 eV) from a nickel target in a vacuum. During one experiment, the nickel surface was badly oxidized because of an accidental break in the vacuum system. After the target was heated in a flowing stream of hydrogen to remove the oxide coating, electrons scattered by it exhibited intensity maxima and minima at specific angles. The experimenters finally realized that the nickel had formed large crystalline regions upon heating and that the regularly spaced planes of atoms in these regions served as a diffraction grating for electrons. (See the discussion of diffraction of x-rays by crystals in Section 38.5.)

Shortly thereafter, Davisson and Germer performed more extensive diffraction measurements on electrons scattered from single-crystal targets. Their results showed conclusively the wave nature of electrons and confirmed the de Broglie relationship \( p = h/\lambda \). In the same year, G. P. Thomson (1892–1975) of Scotland also observed electron diffraction patterns by passing electrons through very thin gold films.

---

*Pitfall Prevention 40.3*

**What’s Waving?** If particles have wave properties, what’s waving? You are familiar with waves on strings, which are very concrete. Sound waves are more abstract, but you are likely comfortable with them. Electromagnetic waves are even more abstract, but at least they can be described in terms of physical variables and electric and magnetic fields. In contrast, waves associated with particles are completely abstract and cannot be associated with a physical variable. In Chapter 41, we describe the wave associated with a particle in terms of probability.

---

*The de Broglie wavelength for a particle moving at any speed \( u \) is \( \lambda = \frac{h}{mu} \), where \( \gamma = \sqrt{1 - \left(\frac{u^2}{c^2}\right)}^{-1/2}. \)
foils. Diffraction patterns were subsequently observed in the scattering of helium atoms, hydrogen atoms, and neutrons. Hence, the wave nature of particles has been established in various ways.

Quick Quiz 40.6 An electron and a proton both moving at nonrelativistic speeds have the same de Broglie wavelength. Which of the following quantities are also the same for the two particles? (a) speed (b) kinetic energy (c) momentum (d) frequency

Example 40.5  Wavelengths for Microscopic and Macroscopic Objects

(A) Calculate the de Broglie wavelength for an electron \((m_e = 9.11 \times 10^{-31} \text{ kg})\) moving at \(1.00 \times 10^7 \text{ m/s}\).

Solution

**Conceptualize** Imagine the electron moving through space. From a classical viewpoint, it is a particle under constant velocity. From the quantum viewpoint, the electron has a wavelength associated with it.

**Categorize** We evaluate the result using an equation developed in this section, so we categorize this example as a substitution problem.

Evaluate the de Broglie wavelength using Equation 40.17:

\[
\lambda = \frac{h}{m_u} = \frac{6.626 \times 10^{-34} \text{ J} \cdot \text{s}}{(9.11 \times 10^{-31} \text{ kg})(1.00 \times 10^7 \text{ m/s})} = 7.27 \times 10^{-11} \text{ m}
\]

The wave nature of this electron could be detected by diffraction techniques such as those in the Davisson–Germer experiment.

(B) A rock of mass 50 g is thrown with a speed of 40 m/s. What is its de Broglie wavelength?

Solution

Evaluate the de Broglie wavelength using Equation 40.17:

\[
\lambda = \frac{h}{m_u} = \frac{6.626 \times 10^{-34} \text{ J} \cdot \text{s}}{(50 \times 10^{-3} \text{ kg})(40 \text{ m/s})} = 3.3 \times 10^{-34} \text{ m}
\]

This wavelength is much smaller than any aperture through which the rock could possibly pass. Hence, we could not observe diffraction effects, and as a result, the wave properties of large-scale objects cannot be observed.

The Electron Microscope

A practical device that relies on the wave characteristics of electrons is the electron microscope. A transmission electron microscope, used for viewing flat, thin samples, is shown in Figure 40.16 on page 1252. In many respects, it is similar to an optical microscope; the electron microscope, however, has a much greater resolving power because it can accelerate electrons to very high kinetic energies, giving them very short wavelengths. No microscope can resolve details that are significantly smaller than the wavelength of the waves used to illuminate the object. The shorter wavelengths of electrons gives an electron microscope a resolution that can be 1000 times better than that from the visible light used in optical microscopes. As a result, an electron microscope with ideal lenses would be able to distinguish details approximately 1000 times smaller than those distinguished by an optical microscope. (Electromagnetic radiation of the same wavelength as the electrons in an electron microscope is in the x-ray region of the spectrum.)

The electron beam in an electron microscope is controlled by electrostatic or magnetic deflection, which acts on the electrons to focus the beam and form an image. Rather than examining the image through an eyepiece as in an optical microscope, the viewer looks at an image formed on a monitor or other type of...
40.6 A New Model: The Quantum Particle

Because in the past we considered the particle and wave models to be distinct, the discussions presented in previous sections may be quite disturbing. The notion that both light and material particles have both particle and wave properties does not fit with this distinction. Experimental evidence shows, however, that this conclusion is exactly what we must accept. The recognition of this dual nature leads to a new model, the quantum particle, which is a combination of the particle model introduced in Chapter 2 and the wave model discussed in Chapter 16. In this new model, entities have both particle and wave characteristics, and we must choose one appropriate behavior—particle or wave—to understand a particular phenomenon.

In this section, we shall explore this model in a way that might make you more comfortable with this idea. We shall do so by demonstrating that an entity that exhibits properties of a particle can be constructed from waves.

Let’s first recall some characteristics of ideal particles and ideal waves. An ideal particle has zero size. Therefore, an essential feature of a particle is that it is localized in space. An ideal wave has a single frequency and is infinitely long as suggested by Figure 40.18a. Therefore, an ideal wave is unlocalized in space. A localized entity can be built from infinitely long waves as follows. Imagine drawing one wave along the $x$ axis, with one of its crests located at $x = 0$, as at the top of Figure 40.18b. Now draw a second wave, of the same amplitude but a different frequency, with one of its

Figure 40.17 A scanning electron microscope photograph shows significant detail of a cheese mite, Tyrolichus casei. The mite is so small, with a maximum length of 0.70 mm, that ordinary microscopes do not reveal minute anatomical details.
crests also at \( x = 0 \). As a result of the superposition of these two waves, beats exist as the waves are alternately in phase and out of phase. (Beats were discussed in Section 18.7.) The bottom curve in Figure 40.18b shows the results of superposing these two waves.

Notice that we have already introduced some localization by superposing the two waves. A single wave has the same amplitude everywhere in space; no point in space is any different from any other point. By adding a second wave, however, there is something different about the in-phase points compared with the out-of-phase points.

Now imagine that more and more waves are added to our original two, each new wave having a new frequency. Each new wave is added so that one of its crests is at \( x = 0 \) with the result that all the waves add constructively at \( x = 0 \). When we add a large number of waves, the probability of a positive value of a wave function at any point \( x \neq 0 \) is equal to the probability of a negative value, and there is destructive interference everywhere except near \( x = 0 \), where all the crests are superposed. The result is shown in Figure 40.19. The small region of constructive interference is called a wave packet. This localized region of space is different from all other regions. We can identify the wave packet as a particle because it has the localized nature of a particle! The location of the wave packet corresponds to the particle’s position.

The localized nature of this entity is the only characteristic of a particle that was generated with this process. We have not addressed how the wave packet might achieve such particle characteristics as mass, electric charge, and spin. Therefore, you may not be completely convinced that we have built a particle. As further evidence that the wave packet can represent the particle, let’s show that the wave packet has another characteristic of a particle.

To simplify the mathematical representation, we return to our combination of two waves. Consider two waves with equal amplitudes but different angular frequencies \( \omega_1 \) and \( \omega_2 \). We can represent the waves mathematically as

\[
y_1 = A \cos (k_1 x - \omega_1 t) \quad \text{and} \quad y_2 = A \cos (k_2 x - \omega_2 t)
\]

where, as in Chapter 16, \( k = 2\pi/\lambda \) and \( \omega = 2\pi f \). Using the superposition principle, let’s add the waves:

\[
y = y_1 + y_2 = A \cos (k_1 x - \omega_1 t) + A \cos (k_2 x - \omega_2 t)
\]

It is convenient to write this expression in a form that uses the trigonometric identity

\[
\cos a + \cos b = 2 \cos \left( \frac{a - b}{2} \right) \cos \left( \frac{a + b}{2} \right)
\]

Letting \( a = k_1 x - \omega_1 t \) and \( b = k_2 x - \omega_2 t \) gives

\[
y = 2A \cos \left( \frac{(k_1 x - \omega_1 t) - (k_2 x - \omega_2 t)}{2} \right) \cos \left( \frac{(k_1 x - \omega_1 t) + (k_2 x - \omega_2 t)}{2} \right)
\]

\[
y = 2A \cos \left( \frac{k_1 - k_2}{2} x - \frac{\Delta \omega}{2} t \right) \cos \left( \frac{k_1 + k_2}{2} x - \frac{\omega_1 + \omega_2}{2} t \right)
\]

(40.19)

Figure 40.18 (a) An idealized wave of an exact single frequency is the same throughout space and time. (b) If two ideal waves with slightly different frequencies are combined, beats result (Section 18.7).

Figure 40.19 If a large number of waves are combined, the result is a wave packet, which represents a particle.
where $\Delta k = k_1 - k_2$ and $\Delta \omega = \omega_1 - \omega_2$. The second cosine factor represents a wave with a wave number and frequency that are equal to the averages of the values for the individual waves.

In Equation 40.19, the factor in square brackets represents the envelope of the wave as shown by the dashed curve in Figure 40.20. This factor also has the mathematical form of a wave. This envelope of the combination can travel through space with a different speed than the individual waves. As an extreme example of this possibility, imagine combining two identical waves moving in opposite directions. The two waves move with the same speed, but the envelope has a speed of zero because we have built a standing wave, which we studied in Section 18.2.

For an individual wave, the speed is given by Equation 16.11,

$$v_{\text{phase}} = \frac{\omega}{k} \quad (40.20)$$

This speed is called the **phase speed** because it is the rate of advance of a crest on a single wave, which is a point of fixed phase. Equation 40.20 can be interpreted as follows: the phase speed of a wave is the ratio of the coefficient of the time variable $t$ to the coefficient of the space variable $x$ in the equation representing the wave, $y = A \cos (kx - \omega t)$.

The factor in brackets in Equation 40.19 is of the form of a wave, so it moves with a speed given by this same ratio:

$$v_g = \frac{\text{coefficient of time variable } t}{\text{coefficient of space variable } x} = \frac{(\Delta \omega / 2)}{(\Delta k / 2)} = \frac{\Delta \omega}{\Delta k}$$

The subscript $g$ on the speed indicates that it is commonly called the **group speed**, or the speed of the wave packet (the group of waves) we have built. We have generated this expression for a simple addition of two waves. When a large number of waves are superposed to form a wave packet, this ratio becomes a derivative:

$$v_g = \frac{d \omega}{dk} \quad (40.21)$$

Multiplying the numerator and the denominator by $h$, where $h = h/2\pi$, gives

$$v_g = \frac{h d\omega}{hdk} = \frac{d(h \omega)}{d(hk)} \quad (40.22)$$

Let’s look at the terms in the parentheses of Equation 40.22 separately. For the numerator,

$$h \omega = \frac{h}{2\pi} (2\pi f) = hf = E$$

For the denominator,

$$hk = \frac{h}{2\pi} \left( \frac{2\pi}{\lambda} \right) = \frac{h}{\lambda} = p$$
Therefore, Equation 40.22 can be written as

\[ v_g = \frac{d(h \omega)}{d(\hbar k)} = \frac{dE}{dp} \quad (40.23) \]

Because we are exploring the possibility that the envelope of the combined waves represents the particle, consider a free particle moving with a speed \( u \) that is small compared with the speed of light. The energy of the particle is its kinetic energy:

\[ E = \frac{1}{2}mu^2 = \frac{\hat{p}^2}{2m} \]

Differentiating this equation with respect to \( \hat{p} \) gives

\[ v_g = \frac{dE}{dp} = \frac{d}{dp} \left( \frac{\hat{p}^2}{2m} \right) = \frac{1}{2m} (2\hat{p}) = u \quad (40.24) \]

Therefore, the group speed of the wave packet is identical to the speed of the particle that it is modeled to represent, giving us further confidence that the wave packet is a reasonable way to build a particle.

Quick Quiz 40.7 As an analogy to wave packets, consider an “automobile packet” that occurs near the scene of an accident on a freeway. The phase speed is analogous to the speed of individual automobiles as they move through the backup caused by the accident. The group speed can be identified as the speed of the leading edge of the packet of cars. For the automobile packet, is the group speed (a) the same as the phase speed, (b) less than the phase speed, or (c) greater than the phase speed?

40.7 The Double-Slit Experiment Revisited

Wave–particle duality is now a firmly accepted concept reinforced by experimental results, including those of the Davisson–Germer experiment. As with the postulates of special relativity, however, this concept often leads to clashes with familiar thought patterns we hold from everyday experience.

One way to crystallize our ideas about the electron’s wave–particle duality is through an experiment in which electrons are fired at a double slit. Consider a parallel beam of mono-energetic electrons incident on a double slit as in Figure 40.21. Let’s assume the slit widths are small compared with the electron wavelength so that we need not worry about diffraction maxima and minima as discussed for light in Section 38.2. An electron detector screen is positioned far from the slits at a distance much greater than \( d \), the separation distance of the slits. If the detector screen collects electrons for a long enough time, we find a typical wave interference pattern for the counts per minute, or probability of arrival of electrons. Such an interference pattern is illustrated in Figure 40.21.
pattern would not be expected if the electrons behaved as classical particles, giving clear evidence that electrons are interfering, a distinct wave-like behavior.

If we measure the angles \( \theta \) at which the maximum intensity of electrons arrives at the detector screen in Figure 40.21, we find they are described by exactly the same equation as that for light, \( d \sin \theta = m\lambda \) (Eq. 37.2), where \( m \) is the order number and \( \lambda \) is the electron wavelength. Therefore, the dual nature of the electron is clearly shown in this experiment: the electrons are detected as particles at a localized spot on the detector screen at some instant of time, but the probability of arrival at that spot is determined by finding the intensity of two interfering waves.

Now imagine that we lower the beam intensity so that one electron at a time arrives at the double slit. It is tempting to assume the electron goes through either slit 1 or slit 2. You might argue that there are no interference effects because there is not a second electron going through the other slit to interfere with the first. This assumption places too much emphasis on the particle model of the electron, however. The interference pattern is still observed if the time interval for the measurement is sufficiently long for many electrons to pass one at a time through the slits and arrive at the detector screen! This situation is illustrated by the computer-simulated patterns in Figure 40.22 where the interference pattern becomes clearer as the number of electrons reaching the detector screen increases. Hence, our assumption that the electron is localized and goes through only one slit when both slits are open must be wrong (a painful conclusion!).

To interpret these results, we are forced to conclude that an electron interacts with both slits simultaneously. If you try to determine experimentally which slit the electron goes through, the act of measuring destroys the interference pattern. It is impossible to determine which slit the electron goes through. In effect, we can say only that the electron passes through both slits! The same arguments apply to photons.

If we restrict ourselves to a pure particle model, it is an uncomfortable notion that the electron can be present at both slits at once. From the quantum particle model, however, the particle can be considered to be built from waves that exist throughout space. Therefore, the wave components of the electron are present at both slits at the same time, and this model leads to a more comfortable interpretation of this experiment.

### 40.8 The Uncertainty Principle

Whenever one measures the position or velocity of a particle at any instant, experimental uncertainties are built into the measurements. According to classical mechanics, there is no fundamental barrier to an ultimate refinement of the apparatus or experimental procedures. In other words, it is possible, in principle, to make such measurements with arbitrarily small uncertainty. Quantum theory predicts, however, that it is fundamentally impossible to make simultaneous measurements of a particle’s position and momentum with infinite accuracy.

In 1927, Werner Heisenberg (1901–1976) introduced this notion, which is now known as the Heisenberg uncertainty principle:

If a measurement of the position of a particle is made with uncertainty \( \Delta x \) and a simultaneous measurement of its \( x \) component of momentum is made with uncertainty \( \Delta p_x \), the product of the two uncertainties can never be smaller than \( \hbar /2 \):

\[
\Delta x \Delta p_x \geq \frac{\hbar}{2} \quad (40.25)
\]

That is, it is physically impossible to measure simultaneously the exact position and exact momentum of a particle. Heisenberg was careful to point out that the inescapable uncertainties \( \Delta x \) and \( \Delta p_x \) do not arise from imperfections in practical measuring instruments. Rather, the uncertainties arise from the quantum structure of matter.
To understand the uncertainty principle, imagine that a particle has a single wavelength that is known exactly. According to the de Broglie relation, $\lambda = \frac{h}{p}$, we would therefore know the momentum to be precisely $p = \frac{h}{\lambda}$. In reality, a single-wavelength wave would exist throughout space. Any region along this wave is the same as any other region (Fig. 40.18a). Suppose we ask, Where is the particle this wave represents? No special location in space along the wave could be identified with the particle; all points along the wave are the same. Therefore, we have infinite uncertainty in the position of the particle, and we know nothing about its location. Perfect knowledge of the particle’s momentum has cost us all information about its location.

In comparison, now consider a particle whose momentum is uncertain so that it has a range of possible values of momentum. According to the de Broglie relation, the result is a range of wavelengths. Therefore, the particle is not represented by a single wavelength, but rather by a combination of wavelengths within this range. This combination forms a wave packet as we discussed in Section 40.6 and illustrated in Figure 40.19. If you were asked to determine the location of the particle, you could only say that it is somewhere in the region defined by the wave packet because there is a distinct difference between this region and the rest of space. Therefore, by losing some information about the momentum of the particle, we have gained information about its position.

If you were to lose all information about the momentum, you would be adding together waves of all possible wavelengths, resulting in a wave packet of zero length. Therefore, if you know nothing about the momentum, you know exactly where the particle is.

The mathematical form of the uncertainty principle states that the product of the uncertainties in position and momentum is always larger than some minimum value. This value can be calculated from the types of arguments discussed above, and the result is the value of $\Delta E \Delta t \geq \frac{h}{2}$ in Equation 40.25.

Another form of the uncertainty principle can be generated by reconsidering Figure 40.19. Imagine that the horizontal axis is time rather than spatial position $x$. We can then make the same arguments that were made about knowledge of wavelength and position in the time domain. The corresponding variables would be frequency and time. Because frequency is related to the energy of the particle by $E = hf$, the uncertainty principle in this form is

$$\Delta E \Delta t \geq \frac{h}{2}$$

The form of the uncertainty principle given in Equation 40.26 suggests that energy conservation can appear to be violated by an amount $\Delta E$ as long as it is only for a short time interval $\Delta t$ consistent with that equation. We shall use this notion to estimate the rest energies of particles in Chapter 46.

Quick Quiz 40.8 A particle’s location is measured and specified as being exactly at $x = 0$, with zero uncertainty in the $x$ direction. How does that location affect the uncertainty of its velocity component in the $y$ direction? (a) It does not affect it. (b) It makes it infinite. (c) It makes it zero.

Example 40.6 Locating an Electron

The speed of an electron is measured to be $5.00 \times 10^3$ m/s to an accuracy of 0.003 00%. Find the minimum uncertainty in determining the position of this electron.

Solution

Conceptualize The fractional value given for the accuracy of the electron’s speed can be interpreted as the fractional uncertainty in its momentum. This uncertainty corresponds to a minimum uncertainty in the electron’s position through the uncertainty principle.
Introduction to Quantum Physics

Solve Equation 40.25 for the uncertainty in the electron’s position and substitute numerical values:

\[
\Delta x = \frac{\hbar}{2mfv_x} = \frac{1.055 \times 10^{-34} \text{ J} \cdot \text{s}}{2(9.11 \times 10^{-31} \text{ kg})(0.0000300)(5.00 \times 10^3 \text{ m/s})}
\]

\[= 3.86 \times 10^{-4} \text{ m} = 0.386 \text{ mm}\]

Assume the electron is moving along the x axis and find the uncertainty in \(p_x\), letting \(f\) represent the accuracy of the measurement of its speed:

\[\Delta x \geq \frac{\hbar}{2 \Delta p_x} = \frac{\hbar}{2mfv_x} = 3.86 \times 10^{-4} \text{ m} = 0.386 \text{ mm}\]

Example 40.7 The Line Width of Atomic Emissions

Atoms have quantized energy levels similar to those of Planck’s oscillators, although the energy levels of an atom are usually not evenly spaced. When an atom makes a transition between states separated in energy by \(\Delta E\), energy is emitted in the form of a photon of frequency \(f = \Delta E/h\). Although an excited atom can radiate at any time from \(t = 0\) to \(t = \infty\), the average time interval after excitation during which an atom radiates is called the lifetime \(\tau\). If \(\tau = 1.0 \times 10^{-8} \text{ s}\), use the uncertainty principle to compute the line width \(\Delta f\) produced by this finite lifetime.

Conceptualize The lifetime \(\tau\) given for the excited state can be interpreted as the uncertainty \(\Delta t\) in the time at which the transition occurs. This uncertainty corresponds to a minimum uncertainty in the frequency of the radiated photon through the uncertainty principle.

Categorize We evaluate the result using concepts developed in this section, so we categorize this example as a substitution problem.

Solution

Use Equation 40.5 to relate the uncertainty in the photon’s frequency to the uncertainty in its energy:

\[E = hf \rightarrow \Delta E = h \Delta f \rightarrow \Delta f = \frac{\Delta E}{h}\]

Use Equation 40.26 to substitute for the uncertainty in the photon’s energy, giving the minimum value of \(\Delta f\):

\[\Delta f \geq \frac{1}{h} \frac{\hbar}{2 \Delta t} = \frac{1}{h} \frac{\hbar/2\pi}{2 \Delta \tau} = \frac{1}{4\pi \Delta t} = \frac{1}{4\pi \tau}\]

Substitute for the lifetime of the excited state:

\[\Delta f \geq \frac{1}{4\pi (1.0 \times 10^{-8} \text{ s})} = 8.0 \times 10^6 \text{ Hz}\]

What if? What if this same lifetime were associated with a transition that emits a radio wave rather than a visible light wave from an atom? Is the fractional line width \(\Delta f/f\) larger or smaller than for the visible light?

Answer Because we are assuming the same lifetime for both transitions, \(\Delta f\) is independent of the frequency of radiation. Radio waves have lower frequencies than light waves, so the ratio \(\Delta f/f\) will be larger for the radio waves. Assuming a light-wave frequency \(f\) of \(6.00 \times 10^{14} \text{ Hz}\), the fractional line width is

\[\Delta f = 8.0 \times 10^6 \text{ Hz} \quad 6.00 \times 10^{14} \text{ Hz} = 1.3 \times 10^{-8}\]

This narrow fractional line width can be measured with a sensitive interferometer. Usually, however, temperature and pressure effects overshadow the natural line width and broaden the line through mechanisms associated with the Doppler effect and collisions.

Assuming a radio-wave frequency \(f\) of \(94.7 \times 10^6 \text{ Hz}\), the fractional line width is

\[\Delta f = 8.0 \times 10^6 \text{ Hz} \quad 94.7 \times 10^6 \text{ Hz} = 8.4 \times 10^{-2}\]

Therefore, for the radio wave, this same absolute line width corresponds to a fractional line width of more than 8%.
The photoelectric effect is a process whereby electrons are ejected from a metal surface when light is incident on that surface. In Einstein’s model, light is viewed as a stream of particles, or photons, each having energy \( E = hf \), where \( h \) is Planck’s constant and \( f \) is the frequency. The maximum kinetic energy of the ejected photoelectron is
\[
K_{\text{max}} = hf - \phi
\]
where \( \phi \) is the work function of the metal.

X-rays are scattered at various angles by electrons in a target. In such a scattering event, a shift in wavelength is observed for the scattered x-rays, a phenomenon known as the Compton effect. Classical physics does not predict the correct behavior in this effect. If the x-ray is treated as a photon, conservation of energy and linear momentum applied to the photon–electron collisions yields, for the Compton shift,
\[
\lambda' - \lambda_o = \frac{h}{m_e c} (1 - \cos \theta)
\]
where \( m_e \) is the mass of the electron, \( c \) is the speed of light, and \( \theta \) is the scattering angle.

Every object of mass \( m \) and momentum \( p = mu \) has wave properties, with a de Broglie wavelength given by
\[
\lambda = \frac{h}{p} = \frac{h}{mu}
\]

The Heisenberg uncertainty principle states that if a measurement of the position of a particle is made with uncertainty \( \Delta x \) and a simultaneous measurement of its linear momentum is made with uncertainty \( \Delta p_x \), the product of the two uncertainties is restricted to
\[
\Delta x \Delta p_x \geq \frac{h}{2}
\]
Another form of the uncertainty principle relates measurements of energy and time:
\[
\Delta E \Delta t \geq \frac{h}{2}
\]
kinetic energy 3 eV (c) a proton with kinetic energy 3 eV (d) a photon with energy 0.3 eV (e) an electron with momentum 3 eV/c

2. An x-ray photon is scattered by an originally stationary electron. Relative to the frequency of the incident photon, is the frequency of the scattered photon (a) lower, (b) higher, or (c) unchanged?

3. In a Compton scattering experiment, a photon of energy \( E \) is scattered from an electron at rest. After the scattering event occurs, which of the following statements is true? (a) The frequency of the photon is greater than \( E/h \). (b) The energy of the photon is less than \( E \). (c) The wavelength of the photon is less than \( \hbar c/E \). (d) The momentum of the photon increases. (e) None of those statements is true.

4. In a certain experiment, a filament in an evacuated lightbulb carries a current \( I_1 \) and you measure the spectrum of light emitted by the filament, which behaves as a black body at temperature \( T_1 \). The wavelength emitted with highest intensity (symbolized by \( \lambda_{\text{max}} \)) has the value \( \lambda_1 \). You then increase the potential difference across the filament by a factor of 8, and the current increases by a factor of 2. (i) After this change, what is the new value of the temperature of the filament? (a) 16\( T_1 \) (b) 8\( T_1 \) (c) 4\( T_1 \) (d) 2\( T_1 \) (e) still \( T_1 \) (ii) What is the new value of the wavelength emitted with highest intensity? (a) 4\( \lambda_1 \) (b) 2\( \lambda_1 \) (c) \( \lambda_1 \) (d) \( \frac{1}{2} \lambda_1 \) (e) \( \frac{1}{4} \lambda_1 \)

5. Which of the following statements are true according to the uncertainty principle? More than one statement may be correct. (a) It is impossible to simultaneously determine both the position and the momentum of a particle along the same axis with arbitrary accuracy. (b) It is impossible to simultaneously determine both the energy and momentum of a particle with arbitrary accuracy. (c) It is possible to determine a particle’s energy with arbitrary accuracy in a finite amount of time. (d) It is impossible to measure the position of a particle with arbitrary accuracy in a finite amount of time. (e) It is impossible to simultaneously measure both the energy and position of a particle with arbitrary accuracy.

6. A monochromatic light beam is incident on a barium target that has a work function of 2.50 eV. If a potential difference of 1.00 V is required to turn back all the ejected electrons, what is the wavelength of the light beam? (a) 355 nm (b) 497 nm (c) 744 nm (d) 1.42 pm (e) none of those answers

7. Which of the following is most likely to cause sunburn by delivering more energy to individual molecules in skin cells? (a) infrared light (b) visible light (c) ultraviolet light (d) microwaves (e) Choices (a) through (d) are equally likely.

8. Which of the following phenomena most clearly demonstrates the wave nature of electrons? (a) the photoelectric effect (b) blackbody radiation (c) the Compton effect (d) diffraction of electrons by crystals (e) none of those answers

9. What is the de Broglie wavelength of an electron accelerated from rest through a potential difference of 50.0 V? (a) 0.100 nm (b) 0.139 nm (c) 0.174 nm (d) 0.834 nm (e) none of those answers

10. A proton, an electron, and a helium nucleus all move at speed \( v \). Rank their de Broglie wavelengths from largest to smallest.

11. Consider (a) an electron, (b) a photon, and (c) a proton, all moving in vacuum. Choose all correct answers for each question. (i) Which of the three possess rest energy? (ii) Which have charge? (iii) Which carry energy? (iv) Which carry momentum? (v) Which move at the speed of light? (vi) Which have a wavelength characterizing their motion?

12. An electron and a proton, moving in opposite directions, are accelerated from rest through the same potential difference. Which particle has the longer wavelength? (a) The electron does. (b) The proton does. (c) Both are the same. (d) Neither has a wavelength.

13. Which of the following phenomena most clearly demonstrates the particle nature of light? (a) diffraction (b) the photoelectric effect (c) polarization (d) interference (e) refraction

14. Both an electron and a proton are accelerated to the same speed, and the experimental uncertainty in the speed is the same for the two particles. The positions of the two particles are also measured. Is the minimum possible uncertainty in the electron’s position (a) less than the minimum possible uncertainty in the proton’s position, (b) the same as that for the proton, (c) more than that for the proton, or (d) impossible to tell from the given information?

Conceptual Questions

1. The opening photograph for this chapter shows a filament of a lightbulb in operation. Look carefully at the last turns of wire at the upper and lower ends of the filament. Why are these turns dimmer than the others?

2. How does the Compton effect differ from the photoelectric effect?

3. If matter has a wave nature, why is this wave-like characteristic not observable in our daily experiences?

4. If the photoelectric effect is observed for one metal, can you conclude that the effect will also be observed for another metal under the same conditions? Explain.

5. In the photoelectric effect, explain why the stopping potential depends on the frequency of light but not on the intensity.

6. Why does the existence of a cutoff frequency in the photoelectric effect favor a particle theory for light over a wave theory?

7. Which has more energy, a photon of ultraviolet radiation or a photon of yellow light? Explain.
8. All objects radiate energy. Why, then, are we not able to see all objects in a dark room?

9. Is an electron a wave or a particle? Support your answer by citing some experimental results.

10. Suppose a photograph were made of a person’s face using only a few photons. Would the result be simply a very faint image of the face? Explain your answer.

11. Why is an electron microscope more suitable than an optical microscope for “seeing” objects less than 1 μm in size?

12. Is light a wave or a particle? Support your answer by citing specific experimental evidence.

13. (a) What does the slope of the lines in Figure 40.11 represent? (b) What does the y intercept represent? (c) How would such graphs for different metals compare with one another?

14. Why was the demonstration of electron diffraction by Davisson and Germer an important experiment?

15. Iridescence is the phenomenon that gives shining colors to the feathers of peacocks, hummingbirds (see page 1134), resplendent quetzals, and even ducks and grackles. Without pigments, it colors Morpho butterflies (Fig. CQ40.15), Urania moths, some beetles and flies, rainbow trout, and mother-of-pearl in abalone shells. Iridescent colors change as you turn an object. They are produced by a wide variety of intricate structures in different species. Problem 64 in Chapter 38 describes the structures that produce iridescence in a peacock feather. These structures were all unknown until the invention of the electron microscope. Explain why light microscopes cannot reveal them.

16. In describing the passage of electrons through a slit and arriving at a screen, physicist Richard Feynman said that “electrons arrive in lumps, like particles, but the probability of arrival of these lumps is determined as the intensity of the waves would be. It is in this sense that the electron behaves sometimes like a particle and sometimes like a wave.” Elaborate on this point in your own words. For further discussion, see R. Feynman, *The Character of Physical Law* (Cambridge, MA: MIT Press, 1980), chap. 6.

17. The classical model of blackbody radiation given by the Rayleigh–Jeans law has two major flaws. (a) Identify the flaws and (b) explain how Planck’s law deals with them.
5. The average threshold of dark-adapted (scotopic) vision is $4.00 \times 10^{-11}$ W/m² at a central wavelength of 500 nm. If light with this intensity and wavelength enters the eye and the pupil is open to its maximum diameter of 8.50 mm, how many photons per second enter the eye?

6. (i) Calculate the energy, in electron volts, of a photon whose frequency is (a) 620 THz, (b) 3.10 GHz, and (c) 46.0 MHz. (ii) Determine the corresponding wavelengths for the photons listed in part (i) and (iii) state the classification of each on the electromagnetic spectrum.

7. (a) What is the surface temperature of Betelgeuse, a red giant star in the constellation Orion (Fig. 40.4), which radiates with a peak wavelength of about 970 nm? (b) Rigel, a bluish-white star in Orion, radiates with a peak wavelength of 145 nm. Find the temperature of Rigel’s surface.

8. An FM radio transmitter has a power output of 150 kW and operates at a frequency of 99.7 MHz. How many photons per second does the transmitter emit?

9. The human eye is most sensitive to 560-nm (green) light. What is the temperature of a black body that would radiate most intensely at this wavelength?

10. The radius of our Sun is $6.96 \times 10^8$ m, and its total power output is $3.85 \times 10^{26}$ W. (a) Assuming the Sun’s surface emits as a black body, calculate its surface temperature. (b) Using the result of part (a), find $\lambda_{\text{max}}$ for the Sun.

11. A black body at 7500 K consists of an opening of diameter 0.050 0 mm, looking into an oven. Find the number of photons per second escaping the opening and having wavelengths between 500 nm and 510 nm.

12. Consider a black body of surface area 20.0 cm² and temperature 5000 K. (a) How much power does it radiate? (b) At what wavelength does it radiate most intensely? Find the spectral power per wavelength interval at (c) this wavelength and at wavelengths of (d) 1.00 nm (an x- or gamma ray), (e) 5.00 nm (ultraviolet light or an x-ray), (f) 400 nm (at the boundary between UV and visible light), (g) 700 nm (at the boundary between visible and infrared light), (h) 1.00 mm (infrared light or a microwave), and (i) 10.0 cm (a microwave or radio wave). (j) Approximately how much power does the object radiate as visible light?

13. Review. This problem is about how strongly matter is coupled to radiation, the subject with which quantum mechanics began. For a simple model, consider a solid iron sphere 2.00 cm in radius. Assume its temperature is always uniform throughout its volume. (a) Find the mass of the sphere. (b) Assume the sphere is at 20.0°C and has emissivity 0.860. Find the power with which it radiates electromagnetic waves. (c) If it were alone in the Universe, at what rate would the sphere’s temperature be changing? (d) Assume Wien’s law describes the sphere. Find the wavelength $\lambda_{\text{max}}$ of electromagnetic radiation it emits most strongly. Although it emits a spectrum of waves having all different wavelengths, assume its power output is carried by photons of wavelength $\lambda_{\text{max}}$. Find (e) the energy of one photon and (f) the number of photons it emits each second.

14. Show that at long wavelengths, Planck’s radiation law (Eq. 40.6) reduces to the Rayleigh–Jeans law (Eq. 40.3).

15. A simple pendulum has a length of 1.00 m and a mass of 1.00 kg. The maximum horizontal displacement of the pendulum bob from equilibrium is 3.00 cm. Calculate the quantum number $n$ for the pendulum.

16. A pulsed ruby laser emits light at 694.3 nm. For a 14.0-ps pulse containing 3.00 J of energy, find (a) the physical length of the pulse as it travels through space and (b) the number of photons in it. (c) Assuming that the beam has a circular cross-section of 0.600 cm diameter, find the number of photons per cubic millimeter.

Section 40.2 The Photoelectric Effect

17. Molybdenum has a work function of 4.20 eV. (a) Find the cutoff wavelength and cutoff frequency for the photoelectric effect. (b) What is the stopping potential if the incident light has a wavelength of 180 nm?

18. The work function for zinc is 4.31 eV. (a) Find the cutoff wavelength for zinc. (b) What is the lowest frequency of light incident on zinc that releases photoelectrons from its surface? (c) If photons of energy 5.50 eV are incident on zinc, what is the maximum kinetic energy of the ejected photoelectrons?

19. Two light sources are used in a photoelectric experiment to determine the work function for a particular metal surface. When green light from a mercury lamp ($\lambda = 546.1$ nm) is used, a stopping potential of 0.376 V reduces the photocurrent to zero. (a) Based on this measurement, what is the work function for this metal? (b) What stopping potential would be observed when using the yellow light from a helium discharge tube ($\lambda = 587.5$ nm)?

20. Lithium, beryllium, and mercury have work functions of 2.30 eV, 3.90 eV, and 4.50 eV, respectively. Light with a wavelength of 400 nm is incident on each of these metals. (a) Determine which of these metals exhibit the photoelectric effect for this incident light. Explain your reasoning. (b) Find the maximum kinetic energy for the photoelectrons in each case.

21. Electrons are ejected from a metallic surface with speeds of up to $4.60 \times 10^3$ m/s when light with a wavelength of 625 nm is used. (a) What is the work function of the surface? (b) What is the cutoff frequency for this surface?

22. From the scattering of sunlight, J. J. Thomson calculated the classical radius of the electron as having the value $2.82 \times 10^{-15}$ m. Sunlight with an intensity of 500 W/m² falls on a disk with this radius. Assume light is a classical wave and the light striking the disk is completely absorbed. (a) Calculate the time interval required to accumulate 1.00 eV of energy. (b) Explain how your result for part (a) compares with the observation that photoelectrons are emitted promptly (within $10^{-8}$ s).
23. **Review.** An isolated copper sphere of radius 5.00 cm, initially uncharged, is illuminated by ultraviolet light of wavelength 200 nm. The work function for copper is 4.70 eV. What charge does the photoelectric effect induce on the sphere?

24. The work function for platinum is 6.35 eV. Ultraviolet light of wavelength 150 nm is incident on the clean surface of a platinum sample. We wish to predict the stopping voltage we will need for electrons ejected from the surface. (a) What is the photon energy of the ultraviolet light? (b) How do you know that these photons will eject electrons from platinum? (c) What is the maximum kinetic energy of the ejected photoelectrons? (d) What stopping voltage would be required to arrest the current of photoelectrons?

**Section 40.3 The Compton Effect**

25. X-rays are scattered from a target at an angle of 55.0° with the direction of the incident beam. Find the wavelength shift of the scattered x-rays.

26. A photon having wavelength \( \lambda \) scatters off a free electron at \( A \) (Fig. P40.26), producing a second photon having wavelength \( \lambda' \). This photon then scatters off another free electron at \( B \), producing a third photon having wavelength \( \lambda'' \) and moving in a direction directly opposite the original photon as shown in the figure. Determine the value of \( \Delta \lambda = \lambda'' - \lambda \).

![Figure P40.26](image)

27. A 0.110-nm photon collides with a stationary electron. After the collision, the electron moves forward and the photon recoils backward. Find the momentum and the kinetic energy of the electron.

28. X-rays with a wavelength of 120.0 pm undergo Compton scattering. (a) Find the wavelengths of the photons scattered at angles of 30.0°, 60.0°, 90.0°, 120°, 150°, and 180°. (b) Find the energy of the scattered electron in each case. (c) Which of the scattering angles provides the electron with the greatest energy? Explain whether you could answer this question without doing any calculations.

29. A 0.001 60-nm photon scatters from a free electron. For what (photon) scattering angle does the recoiling electron have kinetic energy equal to the energy of the scattered photon?

30. After a 0.800-nm x-ray photon scatters from a free electron, the electron recoils at \( 1.40 \times 10^6 \) m/s. (a) What is the Compton shift in the photon’s wavelength? (b) Through what angle is the photon scattered?

31. A photon having energy \( E_0 = 0.880 \text{ MeV} \) is scattered by a free electron initially at rest such that the scattering angle of the scattered electron is equal to that of the scattered photon as shown in Figure P40.31. (a) Determine the scattering angle of the photon and the electron. (b) Determine the energy and momentum of the scattered photon. (c) Determine the kinetic energy and momentum of the scattered electron.

![Figure P40.31](image)

32. A photon having energy \( E_0 \) is scattered by a free electron initially at rest such that the scattering angle of the scattered electron is equal to that of the scattered photon as shown in Figure P40.31. (a) Determine the angle \( \theta \). (b) Determine the energy and momentum of the scattered photon. (c) Determine the kinetic energy and momentum of the scattered electron.

33. X-rays having an energy of 300 keV undergo Compton scattering from a target. The scattered rays are detected at 37.0° relative to the incident rays. Find (a) the Compton shift at this angle, (b) the energy of the scattered x-ray, and (c) the energy of the recoiling electron.

34. In a Compton scattering experiment, a photon is scattered through an angle of 90.0° and the electron is set into motion in a direction at an angle of 20.0° to the original direction of the photon. (a) Explain how this information is sufficient to determine uniquely the wavelength of the scattered photon and (b) find this wavelength.

35. In a Compton scattering experiment, an x-ray photon scatters through an angle of 17.4° from a free electron that is initially at rest. The electron recoils with a speed of 2 180 km/s. Calculate (a) the wavelength of the incident photon and (b) the angle through which the electron scatters.

36. Find the maximum fractional energy loss for a 0.511-MeV gamma ray that is Compton scattered from (a) a free electron and (b) a free proton.

**Section 40.4 The Nature of Electromagnetic Waves**

37. An electromagnetic wave is called **ionizing radiation** if its photon energy is larger than, say, 10.0 eV so that a single photon has enough energy to break apart an atom. With reference to Figure P40.37 (page 1264), explain what region or regions of the electromagnetic spectrum fit this definition of ionizing radiation and
what do not. (If you wish to consult a larger version of Fig. P40.37, see Fig. 34.13.)

**Figure P40.37**

**38. Review.** A helium–neon laser produces a beam of diameter 1.75 mm, delivering $2.00 \times 10^{18}$ photons/s. Each photon has a wavelength of 633 nm. Calculate the amplitudes of (a) the electric fields and (b) the magnetic fields inside the beam. (c) If the beam shines perpendicularly onto a perfectly reflecting surface, what force does it exert on the surface? (d) If the beam is absorbed by a block of ice at 0°C for 1.50 h, what mass of ice is melted?

**Section 40.5 The Wave Properties of Particles**

39. (a) Calculate the momentum of a photon whose wavelength is $4.00 \times 10^{-7}$ m. (b) Find the speed of an electron having the same momentum as the photon in part (a).

40. (a) An electron has a kinetic energy of 3.00 eV. Find its wavelength. (b) **What If?** A photon has energy 3.00 eV. Find its wavelength.

41. The resolving power of a microscope depends on the wavelength used. If you wanted to “see” an atom, a wavelength of approximately $1.00 \times 10^{-11}$ m would be required. (a) If electrons are used (in an electron microscope), what minimum kinetic energy is required for the electrons? (b) **What If?** If photons are used, what minimum photon energy is needed to obtain the required resolution?

42. Calculate the de Broglie wavelength for a proton moving with a speed of $1.00 \times 10^6$ m/s.

43. In the Davisson–Germer experiment, 54.0-eV electrons were diffracted from a nickel lattice. If the first maximum in the diffraction pattern was observed at $\phi = 50.0^\circ$ (Fig. P40.43), what was the lattice spacing $a$ between the vertical columns of atoms in the figure?

**Figure P40.43**

44. The nucleus of an atom is on the order of $10^{-14}$ m in diameter. For an electron to be confined to a nucleus, its de Broglie wavelength would have to be on this order of magnitude or smaller. (a) What would be the kinetic energy of an electron confined to this region? (b) Make an order-of-magnitude estimate of the electric potential energy of a system of an electron inside an atomic nucleus. (c) Would you expect to find an electron in a nucleus? Explain.

45. Robert Hofstadter won the 1961 Nobel Prize in Physics for his pioneering work in studying the scattering of 20-GeV electrons from nuclei. (a) What is the $\gamma$ factor for an electron with total energy 20.0 GeV, defined by $\gamma = 1/\sqrt{1 - u^2/c^2}$? (b) Find the momentum of the electron.

46. **Why is the following situation impossible?** After learning about de Broglie’s hypothesis that material particles of momentum $p$ move as waves with wavelength $\lambda = h/p$, an 80-kg student has grown concerned about being diffracted when passing through a doorway of width $w = 75$ cm. Assume significant diffraction occurs when the width of the diffraction aperture is less than ten times the wavelength of the wave being diffracted. Together with his classmates, the student performs precision experiments and finds that he does indeed experience measurable diffraction.

47. A photon has an energy equal to the kinetic energy of an electron with speed $u$, which may be close to the speed of light $c$. (a) Calculate the ratio of the wavelength of the photon to the wavelength of the electron. (b) Evaluate the ratio for the particle speed $u = 0.900c$.

48. (a) **What If?** What would happen to the answer to part (b) if the material particle were a proton instead of an electron? (d) Evaluate the ratio for the particle speed $u = 0.001$ $000c$. (c) What value does the ratio of the wavelengths approach at high particle speeds? (f) At low particle speeds?

49. Consider a freely moving quantum particle with mass $m$ and speed $u$. Its energy is $E = K = \frac{1}{2}mu^2$. (a) Determine the phase speed of the quantum wave representing the particle and (b) show that it is different from the speed at which the particle transports mass and energy.

50. For a free relativistic quantum particle moving with speed $u$, the total energy of the particle is $E = hf = h\omega = \sqrt{p^2c^2 + mc^2}$ and the momentum is $p = h/\lambda = \hbar k = \hbar \omega = \hbar f = hf$. 

**Section 40.6 A New Model: The Quantum Particle**

51. The nucleus of an atom is on the order of $10^{-14}$ m in diameter. For an electron to be confined to a nucleus, its de Broglie wavelength would have to be on this order of magnitude or smaller. (a) What would be the kinetic energy of an electron confined to this region? (b) Make an order-of-magnitude estimate of the electric potential energy of a system of an electron inside an atomic nucleus. (c) Would you expect to find an electron in a nucleus? Explain.

52. Robert Hofstadter won the 1961 Nobel Prize in Physics for his pioneering work in studying the scattering of 20-GeV electrons from nuclei. (a) What is the $\gamma$ factor for an electron with total energy 20.0 GeV, defined by $\gamma = 1/\sqrt{1 - u^2/c^2}$? (b) Find the momentum of the electron.

53. **Why is the following situation impossible?** After learning about de Broglie’s hypothesis that material particles of momentum $p$ move as waves with wavelength $\lambda = h/p$, an 80-kg student has grown concerned about being diffracted when passing through a doorway of width $w = 75$ cm. Assume significant diffraction occurs when the width of the diffraction aperture is less than ten times the wavelength of the wave being diffracted. Together with his classmates, the student performs precision experiments and finds that he does indeed experience measurable diffraction.

54. A photon has an energy equal to the kinetic energy of an electron with speed $u$, which may be close to the speed of light $c$. (a) Calculate the ratio of the wavelength of the photon to the wavelength of the electron. (b) Evaluate the ratio for the particle speed $u = 0.900c$.

55. (a) **What If?** What would happen to the answer to part (b) if the material particle were a proton instead of an electron? (d) Evaluate the ratio for the particle speed $u = 0.001$ $000c$. (c) What value does the ratio of the wavelengths approach at high particle speeds? (f) At low particle speeds?

56. Consider a freely moving quantum particle with mass $m$ and speed $u$. Its energy is $E = K = \frac{1}{2}mu^2$. (a) Determine the phase speed of the quantum wave representing the particle and (b) show that it is different from the speed at which the particle transports mass and energy.

57. For a free relativistic quantum particle moving with speed $u$, the total energy of the particle is $E = hf = h\omega = \sqrt{p^2c^2 + mc^2}$ and the momentum is $p = h/\lambda = \hbar k = \hbar \omega = \hbar f = hf$. 

**Section 40.6 A New Model: The Quantum Particle**

58. The nucleus of an atom is on the order of $10^{-14}$ m in diameter. For an electron to be confined to a nucleus, its de Broglie wavelength would have to be on this order of magnitude or smaller. (a) What would be the kinetic energy of an electron confined to this region? (b) Make an order-of-magnitude estimate of the electric potential energy of a system of an electron inside an atomic nucleus. (c) Would you expect to find an electron in a nucleus? Explain.

59. Robert Hofstadter won the 1961 Nobel Prize in Physics for his pioneering work in studying the scattering of 20-GeV electrons from nuclei. (a) What is the $\gamma$ factor for an electron with total energy 20.0 GeV, defined by $\gamma = 1/\sqrt{1 - u^2/c^2}$? (b) Find the momentum of the electron.

60. **Why is the following situation impossible?** After learning about de Broglie’s hypothesis that material particles of momentum $p$ move as waves with wavelength $\lambda = h/p$, an 80-kg student has grown concerned about being diffracted when passing through a doorway of width $w = 75$ cm. Assume significant diffraction occurs when the width of the diffraction aperture is less than ten times the wavelength of the wave being diffracted. Together with his classmates, the student performs precision experiments and finds that he does indeed experience measurable diffraction.

61. A photon has an energy equal to the kinetic energy of an electron with speed $u$, which may be close to the speed of light $c$. (a) Calculate the ratio of the wavelength of the photon to the wavelength of the electron. (b) Evaluate the ratio for the particle speed $u = 0.900c$.

62. (a) **What If?** What would happen to the answer to part (b) if the material particle were a proton instead of an electron? (d) Evaluate the ratio for the particle speed $u = 0.001$ $000c$. (c) What value does the ratio of the wavelengths approach at high particle speeds? (f) At low particle speeds?

63. Consider a freely moving quantum particle with mass $m$ and speed $u$. Its energy is $E = K = \frac{1}{2}mu^2$. (a) Determine the phase speed of the quantum wave representing the particle and (b) show that it is different from the speed at which the particle transports mass and energy.

64. For a free relativistic quantum particle moving with speed $u$, the total energy of the particle is $E = hf = h\omega = \sqrt{p^2c^2 + mc^2}$ and the momentum is $p = h/\lambda = \hbar k = \hbar \omega = \hbar f = hf$. 

**Section 40.6 A New Model: The Quantum Particle**

65. Consider a freely moving quantum particle with mass $m$ and speed $u$. Its energy is $E = K = \frac{1}{2}mu^2$. (a) Determine the phase speed of the quantum wave representing the particle and (b) show that it is different from the speed at which the particle transports mass and energy.

66. For a free relativistic quantum particle moving with speed $u$, the total energy of the particle is $E = hf = h\omega = \sqrt{p^2c^2 + mc^2}$ and the momentum is $p = h/\lambda = \hbar k = \hbar \omega = \hbar f = hf$. 

**Section 40.6 A New Model: The Quantum Particle**

67. Consider a freely moving quantum particle with mass $m$ and speed $u$. Its energy is $E = K = \frac{1}{2}mu^2$. (a) Determine the phase speed of the quantum wave representing the particle and (b) show that it is different from the speed at which the particle transports mass and energy.
Because of the uncertainty principle, however, after the average lifetime of a muon is about 2 μs. Estimate the minimum uncertainty in the rest energy of a muon.

Why is the following situation impossible? An air rifle is used to shoot 1.00-g particles at a speed of \( v_x = 100 \text{ m/s} \). The rifle’s barrel has a diameter of 2.00 mm. The rifle is mounted on a perfectly rigid support so that it is fired in exactly the same way each time. Because of the uncertainty principle, however, after many firings, the diameter of the spray of pellets on a paper target is 1.00 cm.

Use the uncertainty principle to show that if an electron were confined inside an atomic nucleus of diameter on the order of \( 10^{-15} \text{ m} \), it would have to be moving relativistically, whereas a proton confined to the same nucleus can be moving nonrelativistically.

Additional Problems

The accompanying table shows data obtained in a photoelectric experiment. (a) Using these data, make a graph similar to Figure 40.11 that plots as a straight line. From the graph, determine (b) an experimental value for Planck’s constant (in joule-seconds) and (c) the work function (in electron volts) for the surface. (Two significant figures for each answer are sufficient.)

Photons of wavelength 450 nm are incident on a metal. The most energetic electrons ejected from the metal are bent into a circular arc of radius 20.0 cm by a magnetic field with a magnitude of 2.00 \( \times 10^{-3} \text{ T} \). What is the work function of the metal?

Review. Photons of wavelength \( \lambda \) are incident on a metal. The most energetic electrons ejected from the metal are bent into a circular arc of radius \( R \) by a magnetic field having a magnitude \( B \). What is the work function of the metal?

Review. Design an incandescent lamp filament. A tungsten wire radiates electromagnetic waves with power 75.0 W when its ends are connected across a 120-V power supply. Assume its constant operating temperature is 2900 K and its emissivity is 0.450. Also assume it takes in energy only by electric transmission and emits energy only by electromagnetic radiation. You may take the resistivity of tungsten at 2900 K as \( 7.13 \times 10^{-7} \ \Omega \cdot \text{m} \). Specify (a) the radius and (b) the length of the filament.

Derive the equation for the Compton shift (Eq. 40.13) from Equations 40.14 through 40.16.

Figure P40.65 shows the stopping potential versus the incident photon frequency for the photoelectric effect.
for sodium. Use the graph to find (a) the work function of sodium, (b) the ratio \(h/\alpha\), and (c) the cutoff wavelength. The data are taken from R. A. Millikan, *Physical Review* 7:362 (1916).

66. A photon of initial energy \(E_0\) undergoes Compton scattering at an angle \(\theta\) from a free electron (mass \(m_e\)) initially at rest. Derive the following relationship for the final energy \(E'\) of the scattered photon:

\[
E' = \frac{E_0}{1 + \left(\frac{E_0}{m_e c^2}\right)(1 - \cos \theta)}
\]

67. A daredevil’s favorite trick is to step out of a 16th-story window and fall 50.0 m into a pool. A news reporter takes a picture of the 75.0-kg daredevil just before he makes a splash, using an exposure time of 5.00 ms. Find (a) the daredevil’s de Broglie wavelength at this moment, (b) the uncertainty of his kinetic energy measurement during the 5.00-ms time interval, and (c) the percent error caused by such an uncertainty.

68. Show that the ratio of the Compton wavelength \(\lambda_C\) to the de Broglie wavelength \(\lambda = h/\alpha\) for a relativistic electron is

\[
\frac{\lambda_C}{\lambda} = \left[\frac{E}{m_e c^2} - 1\right]^{1/2}
\]

where \(E\) is the total energy of the electron and \(m_e\) is its mass.

69. Monochromatic ultraviolet light with intensity 550 W/m\(^2\) is incident normally on the surface of a metal that has a work function of 3.44 eV. Photoelectrons are emitted with a maximum speed of 420 km/s. (a) Find the maximum possible rate of photoelectron emission from 1.00 cm\(^2\) of the surface by imagining that every photon produces one photoelectron. (b) Find the electric current these electrons constitute. (c) How do you suppose the actual current compares with this maximum possible current?

70. A \(\pi^0\) meson is an unstable particle produced in high-energy particle collisions. Its rest energy is approximately 135 MeV, and it exists for a lifetime of only \(8.70 \times 10^{-17}\) s before decaying into two gamma rays. Using the uncertainty principle, estimate the fractional uncertainty \(\Delta m/m\) in its mass determination.

71. The neutron has a mass of \(1.67 \times 10^{-27}\) kg. Neutrons emitted in nuclear reactions can be slowed down by collisions with matter. They are referred to as thermal neutrons after they come into thermal equilibrium with the environment. The average kinetic energy \((\frac{1}{2}k_B T)\) of a thermal neutron is approximately 0.04 eV. (a) Calculate the de Broglie wavelength of a neutron with a kinetic energy of 0.040 eV. (b) How does your answer compare with the characteristic atomic spacing in a crystal? (c) Explain whether you expect thermal neutrons to exhibit diffraction effects when scattered by a crystal.

**Challenge Problems**

72. A woman on a ladder drops small pellets toward a point target on the floor. (a) Show that, according to the uncertainty principle, the average miss distance must be at least

\[
\Delta x_f = \left(\frac{2\hbar}{m}\right)^{1/2} \left(\frac{2H}{g}\right)^{1/4}
\]

where \(H\) is the initial height of each pellet above the floor and \(m\) is the mass of each pellet. Assume that the spread in impact points is given by \(\Delta x_f = \Delta x_i + (\Delta v_x)t\). (b) If \(H = 2.00\) m and \(m = 0.500\) g, what is \(\Delta x_f\)?

73. **Review.** A light source emitting radiation at frequency 7.00 \(\times 10^{14}\) Hz is incapable of ejecting photoelectrons from a certain metal. In an attempt to use this source to eject photoelectrons from the metal, the source is given a velocity toward the metal. (a) Explain how this procedure can produce photoelectrons. (b) When the speed of the light source is equal to 0.280c, photoelectrons just begin to be ejected from the metal. What is the work function of the metal? (c) When the speed of the light source is increased to 0.900c, determine the maximum kinetic energy of the photoelectrons.

74. Using conservation principles, prove that a photon cannot transfer all its energy to a free electron.

75. The total power per unit area radiated by a black body at a temperature \(T\) is the area under the \(I(\lambda,T)\)-versus-\(\lambda\) curve as shown in Figure 40.3. (a) Show that this power per unit area is

\[
\int_0^\infty I(\lambda,T) d\lambda = \sigma T^4
\]

where \(I(\lambda,T)\) is given by Planck’s radiation law and \(\sigma\) is a constant independent of \(T\). This result is known as Stefan’s law. (See Section 20.7.) To carry out the integration, you should make the change of variable \(x =hc/\lambda k_B T\) and use

\[
\int_0^\infty x^3 dx = \frac{\pi^4}{15}
\]

(b) Show that the Stefan–Boltzmann constant \(\sigma\) has the value

\[
\sigma = \frac{2\pi^2 k_B^4}{15c^2}\]

76. (a) Derive Wien’s displacement law from Planck’s law. Proceed as follows. In Figure 40.3, notice that the wavelength at which a black body radiates with greatest intensity is the wavelength for which the graph of \(I(\lambda,T)\) versus \(\lambda\) has a horizontal tangent. From Equation 40.6, evaluate the derivative \(dI/d\lambda\). Set it equal to zero. Solve the resulting transcendental equation numerically to prove that \(hc/\lambda_{max}k_B = 4.965\ldots\) or \(\lambda_{max}T = hc/4.965k_B\). (b) Evaluate the constant as precisely as possible and compare it with Wien’s experimental value.
In this chapter, we introduce quantum mechanics, an extremely successful theory for explaining the behavior of microscopic particles. This theory, developed in the 1920s by Erwin Schrödinger, Werner Heisenberg, and others, enables us to understand a host of phenomena involving atoms, molecules, nuclei, and solids. The discussion in this chapter follows from the quantum particle model that was developed in Chapter 40 and incorporates some of the features of the waves under boundary conditions model that was explored in Chapter 18. We also discuss practical applications of quantum mechanics, including the scanning tunneling microscope and nanoscale devices that may be used in future quantum computers. Finally, we shall return to the simple harmonic oscillator that was introduced in Chapter 15 and examine it from a quantum mechanical point of view.

41.1 The Wave Function

In Chapter 40, we introduced some new and strange ideas. In particular, we concluded on the basis of experimental evidence that both matter and electromagnetic radiation are sometimes best modeled as particles and sometimes as waves, depending on the phenomenon being observed. We can improve our understanding of quantum physics by making another connection between particles and waves using the notion of probability, a concept that was introduced in Chapter 40.

We begin by discussing electromagnetic radiation using the particle model. The probability per unit volume of finding a photon in a given region of space at an instant of time is proportional to the number of photons per unit volume at that time:

$$\frac{\text{Probability}}{V} \propto \frac{N}{V}$$
The number of photons per unit volume is proportional to the intensity of the radiation:

\[
\frac{N}{V} \propto I
\]

Now, let’s form a connection between the particle model and the wave model by recalling that the intensity of electromagnetic radiation is proportional to the square of the electric field amplitude \(E\) for the electromagnetic wave (Eq. 34.24):

\[
I \propto E^2
\]

Equating the beginning and the end of this series of proportionalities gives

\[
\frac{\text{Probability}}{V} \propto E^2 \tag{41.1}
\]

Therefore, for electromagnetic radiation, the probability per unit volume of finding a particle associated with this radiation (the photon) is proportional to the square of the amplitude of the associated electromagnetic wave.

Recognizing the wave–particle duality of both electromagnetic radiation and matter, we should suspect a parallel proportionality for a material particle: the probability per unit volume of finding the particle is proportional to the square of the amplitude of a wave representing the particle. In Chapter 40, we learned that there is a de Broglie wave associated with every particle. The amplitude of the de Broglie wave associated with a particle is not a measurable quantity because the wave function representing a particle is generally a complex function as we discuss below. In contrast, the electric field for an electromagnetic wave is a real function. The matter analog to Equation 41.1 relates the square of the amplitude of the wave to the probability per unit volume of finding the particle. Hence, the amplitude of the wave associated with the particle is called the probability amplitude, or the wave function, and it has the symbol \(\Psi\).

In general, the complete wave function \(\Psi\) for a system depends on the positions of all the particles in the system and on time; therefore, it can be written \(\Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_j, \ldots, t)\), where \(\vec{r}_j\) is the position vector of the \(j\)th particle in the system. For many systems of interest, including all those we study in this text, the wave function \(\Psi\) is mathematically separable in space and time and can be written as a product of a space function \(\psi\) for one particle of the system and a complex time function:\(^1\)

\[
\Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_j, \ldots, t) = \psi(\vec{r}_j)e^{-i\omega t} \tag{41.2}
\]

where \(\omega (= 2\pi f)\) is the angular frequency of the wave function and \(i = \sqrt{-1}\).

For any system in which the potential energy is time-independent and depends only on the positions of particles within the system, the important information about the system is contained within the space part of the wave function. The time part is simply the factor \(e^{-i\omega t}\). Therefore, an understanding of \(\psi\) is the critical aspect of a given problem.

The wave function \(\psi\) is often complex-valued. The absolute square \(|\psi|^2 = \psi^*\psi\), where \(\psi^*\) is the complex conjugate\(^2\) of \(\psi\), is always real and positive and is proportional to the probability per unit volume of finding a particle at a given point at some instant. The wave function contains within it all the information that can be known about the particle.

---

\(^1\)The standard form of a complex number is \(a + ib\). The notation \(e^\theta\) is equivalent to the standard form as follows:

\[
e^\theta = \cos \theta + i \sin \theta
\]

Therefore, the notation \(e^{-i\omega t}\) in Equation 41.2 is equivalent to \(\cos (-\omega t) + i \sin (-\omega t) = \cos \omega t - i \sin \omega t\).

\(^2\)For a complex number \(z = a + ib\), the complex conjugate is found by changing \(i\) to \(-i\): \(z^* = a - ib\). The product of a complex number and its complex conjugate is always real and positive. That is, \(z^*z = (a - ib)(a + ib) = a^2 - (ib)^2 = a^2 + b^2\).
Although $\psi$ cannot be measured, we can measure the real quantity $|\psi|^2$, which can be interpreted as follows. If $\psi$ represents a single particle, then $|\psi|^2$—called the probability density—is the relative probability per unit volume that the particle will be found at any given point in the volume. This interpretation can also be stated in the following manner. If $dV$ is a small volume element surrounding some point, the probability of finding the particle in that volume element is

$$P(x, y, z) \, dV = |\psi|^2 \, dV \quad (41.3)$$

This probabilistic interpretation of the wave function was first suggested by Max Born (1882–1970) in 1928. In 1926, Erwin Schrödinger proposed a wave equation that describes the manner in which the wave function changes in space and time. The Schrödinger wave equation, which we shall examine in Section 41.3, represents a key element in the theory of quantum mechanics.

The concepts of quantum mechanics, strange as they sometimes may seem, developed from classical ideas. In fact, when the techniques of quantum mechanics are applied to macroscopic systems, the results are essentially identical to those of classical physics. This blending of the two approaches occurs when the de Broglie wavelength is small compared with the dimensions of the system. The situation is similar to the agreement between relativistic mechanics and classical mechanics when $v \ll c$.

In Section 40.5, we found that the de Broglie equation relates the momentum of a particle to its wavelength through the relation $p = h/\lambda$. If an ideal free particle has a precisely known momentum $p$, its wave function is an infinitely long sinusoidal wave of wavelength $\lambda = h/p$, and the particle has equal probability of being at any point along the $x$ axis (Fig. 40.18a). The wave function $\psi$ for such a free particle moving along the $x$ axis can be written as

$$\psi(x) = Ae^{ikx} \quad (41.4)$$

where $A$ is a constant amplitude and $k = 2\pi/\lambda$ is the angular wave number (Eq. 16.8) of the wave representing the particle.\(^3\)

### One-Dimensional Wave Functions and Expectation Values

This section discusses only one-dimensional systems, where the particle must be located along the $x$ axis, so the probability $|\psi|^2 \, dV$ in Equation 41.3 is modified to become $|\psi|^2 \, dx$. The probability that the particle will be found in the infinitesimal interval $dx$ around the point $x$ is

$$P(x) \, dx = |\psi|^2 \, dx \quad (41.5)$$

Although it is not possible to specify the position of a particle with complete certainty, it is possible through $|\psi|^2$ to specify the probability of observing it in a region surrounding a given point $x$. The probability of finding the particle in the arbitrary interval $a \leq x \leq b$ is

$$P_{ab} = \int_a^b |\psi|^2 \, dx \quad (41.6)$$

The probability $P_{ab}$ is the area under the curve of $|\psi|^2$ versus $x$ between the points $x = a$ and $x = b$ as in Figure 41.1.

Experimentally, there is a finite probability of finding a particle in an interval near some point at some instant. The value of that probability must lie between the

\(^3\)For the free particle, the full wave function, based on Equation 41.2, is

$$\Psi(x, t) = Ae^{ikx - i\omega t} = Ae^{ikx - i\omega t} = A[\cos (kx - \omega t) + i \sin (kx - \omega t)]$$

The real part of this wave function has the same form as the waves we added together to form wave packets in Section 40.6.
limits 0 and 1. For example, if the probability is 0.30, there is a 30% chance of finding the particle in the interval.

Because the particle must be somewhere along the x axis, the sum of the probabilities over all values of x must be 1:

\[ \int_{-\infty}^{\infty} |\psi|^2 \, dx = 1 \]  

Any wave function satisfying Equation 41.7 is said to be normalized. Normalization is simply a statement that the particle exists at some point in space.

Once the wave function for a particle is known, it is possible to calculate the average position at which you would expect to find the particle after many measurements. This average position is called the expectation value of x and is defined by the equation

\[ \langle x \rangle = \int_{-\infty}^{\infty} \psi^* x \psi \, dx \]  

(Brackets, \( \langle \, , \, \rangle \), are used to denote expectation values.) Furthermore, one can find the expectation value of any function \( f(x) \) associated with the particle by using the following equation:

\[ \langle f(x) \rangle = \int_{-\infty}^{\infty} \psi^* f(x) \psi \, dx \]  

Quick Quiz 41.1 Consider the wave function for the free particle, Equation 41.4.

At what value of x is the particle most likely to be found at a given time? (a) at \( x = 0 \) (b) at small nonzero values of x (c) at large values of x (d) anywhere along the x axis

Example 41.1 A Wave Function for a Particle

Consider a particle whose wave function is graphed in Figure 41.2 and is given by

\[ \psi(x) = Ae^{-ax^2} \]

(A) What is the value of A if this wave function is normalized?

Solution

Conceptualize The particle is not a free particle because the wave function is not a sinusoidal function. Figure 41.2 indicates that the particle is constrained to remain close to \( x = 0 \) at all times. Think of a physical system in which the particle always stays close to a given point. Examples of such systems are a block on a spring, a marble at the bottom of a bowl, and the bob of a simple pendulum.

Categorize Because the statement of the problem describes the wave nature of a particle, this example requires a quantum approach rather than a classical approach.

Analyze Apply the normalization condition, Equation 41.7, to the wave function:

\[ \int_{-\infty}^{\infty} |\psi|^2 \, dx = \int_{-\infty}^{\infty} (Ae^{-ax^2})^2 \, dx = A^2 \int_{-\infty}^{\infty} e^{-2ax^2} \, dx = 1 \]

"Expectation values are analogous to "weighted averages," in which each possible value of a function is multiplied by the probability of the occurrence of that value before summing over all possible values. We write the expectation value as \( \int f(x) \psi^* \psi \, dx \) rather than \( \int f(x) \psi \, dx \) because \( f(x) \) may be represented by an operator (such as a derivative) rather than a simple multiplicative function in more advanced treatments of quantum mechanics. In these situations, the operator is applied only to \( \psi \) and not to \( \psi^* \)."
Express the integral as the sum of two integrals:

\[ A^2 \int_{-\infty}^{\infty} e^{-2ax^2} dx = A^2 \left( \int_{0}^{\infty} e^{-2ax^2} dx + \int_{-\infty}^{0} e^{-2ax^2} dx \right) = 1 \]

Change the integration variable from \( x \) to \( -x \) in the second integral:

\[ \int_{-\infty}^{0} e^{-2ax^2} dx = \int_{0}^{\infty} e^{-2a(-x)^2} (-dx) = -\int_{0}^{\infty} e^{-2ax^2} dx \]

Reverse the order of the limits, which introduces a negative sign:

\[ -\int_{0}^{\infty} e^{-2ax^2} dx = \int_{\infty}^{0} e^{-2ax^2} dx \]

Substitute this expression for the second integral in Equation (1):

\[ A^2 \left( \int_{0}^{\infty} e^{-2ax^2} dx + \int_{0}^{\infty} e^{-2ax^2} dx \right) = 1 \]

Evaluate the integral with the help of Table B.6 in Appendix B:

\[ \int_{0}^{\infty} e^{-2ax^2} dx = \frac{\sqrt{\pi}}{2a} \]

Substitute this result into Equation (2) and solve for \( A \):

\[ 2A^2 \left( \frac{\sqrt{\pi}}{2a} \right) = 1 \rightarrow A = \left( \frac{2a}{\pi} \right)^{1/4} \]

**Solution**

Evaluate the expectation value using Equation 41.8:

\[ \langle x \rangle = \int_{-\infty}^{\infty} \psi^* x \psi \, dx = \int_{-\infty}^{\infty} (Ae^{-ax^2})^* x (Ae^{-ax^2}) \, dx \]

\[ = A^2 \int_{-\infty}^{\infty} xe^{-2ax^2} \, dx \]

As in part (A), express the integral as a sum of two integrals:

\[ \langle x \rangle = A^2 \left( \int_{0}^{\infty} xe^{-2ax^2} \, dx + \int_{-\infty}^{0} xe^{-2ax^2} \, dx \right) \]

Change the integration variable from \( x \) to \( -x \) in the second integral:

\[ \int_{-\infty}^{0} xe^{-2ax^2} \, dx = \int_{0}^{\infty} xe^{-2a(-x)^2} (-dx) = \int_{0}^{\infty} xe^{-2ax^2} \, dx \]

Reverse the order of the limits, which introduces a negative sign:

\[ \int_{0}^{\infty} xe^{-2ax^2} \, dx = -\int_{\infty}^{0} xe^{-2ax^2} \, dx \]

Substitute this expression for the second integral in Equation (3):

\[ \langle x \rangle = A^2 \left( \int_{0}^{\infty} xe^{-2ax^2} \, dx - \int_{0}^{\infty} xe^{-2ax^2} \, dx \right) = 0 \]

Finalize: Given the symmetry of the wave function around \( x = 0 \) in Figure 41.2, it is not surprising that the average position of the particle is at \( x = 0 \). In Section 41.7, we show that the wave function studied in this example represents the lowest-energy state of the quantum harmonic oscillator.

**41.2 Analysis Model: Quantum Particle Under Boundary Conditions**

The free particle discussed in Section 41.1 has no boundary conditions; it can be anywhere in space. The particle in Example 41.1 is not a free particle. Figure 41.2 shows that the particle is always restricted to positions near \( x = 0 \). In this section, we shall investigate the effects of restrictions on the motion of a quantum particle.
A Particle in a Box

We begin by applying some of the ideas we have developed to a simple physical problem, a particle confined to a one-dimensional region of space, called the particle-in-a-box problem (even though the “box” is one-dimensional!). From a classical viewpoint, if a particle is bouncing elastically back and forth along the $x$ axis between two impenetrable walls separated by a distance $L$, as in Figure 41.3a, it can be modeled as a particle under constant speed. If the speed of the particle is $u$, the magnitude of its momentum $mu$ remains constant as does its kinetic energy. (Recall that in Chapter 39 we used $u$ for particle speed to distinguish it from $v$, the speed of a reference frame.) Classical physics places no restrictions on the values of a particle’s momentum and energy. The quantum-mechanical approach to this problem is quite different and requires that we find the appropriate wave function consistent with the conditions of the situation.

Because the walls are impenetrable, there is zero probability of finding the particle outside the box, so the wave function $\psi(x)$ must be zero for $x < 0$ and $x > L$. To be a mathematically well-behaved function, $\psi(x)$ must be continuous in space. There must be no discontinuous jumps in the value of the wave function at any point. Therefore, if $\psi$ is zero outside the walls, it must also be zero at the walls; that is, $\psi(0) = 0$ and $\psi(L) = 0$. Only those wave functions that satisfy these boundary conditions are allowed.

Figure 41.3b, a graphical representation of the particle-in-a-box problem, shows the potential energy of the particle–environment system as a function of the position of the particle. As long as the particle is inside the box, the potential energy of the system does not depend on the location of the particle and we can choose its constant value to be zero. Outside the box, we must ensure that the wave function is zero. We can do so by defining the system’s potential energy as infinitely large if the particle were outside the box. Therefore, the only way a particle could be outside the box is if the system has an infinite amount of energy, which is impossible.

The wave function for a particle in the box can be expressed as a real sinusoidal function:

$$\psi(x) = A \sin \left( \frac{2\pi x}{\lambda} \right)$$

(41.10)

where $\lambda$ is the de Broglie wavelength associated with the particle. This wave function must satisfy the boundary conditions at the walls. The boundary condition $\psi(0) = 0$ is satisfied already because the sine function is zero when $x = 0$. The boundary condition $\psi(L) = 0$ gives

$$\psi(L) = 0 = A \sin \left( \frac{2\pi L}{\lambda} \right)$$

which can only be true if

$$\frac{2\pi L}{\lambda} = n\pi \quad \Rightarrow \quad \lambda = \frac{2L}{n}$$

(41.11)

where $n = 1, 2, 3, \ldots$. Therefore, only certain wavelengths for the particle are allowed! Each of the allowed wavelengths corresponds to a quantum state for the system, and $n$ is the quantum number. Incorporating Equation 41.11 in Equation 41.10 gives

$$\psi_n(x) = A \sin \left( \frac{2\pi x}{2L/n} \right) = A \sin \left( \frac{n\pi x}{L} \right)$$

(41.12)

---

5If the wave function were not continuous at a point, the derivative of the wave function at that point would be infinite. This result leads to difficulties in the Schrödinger equation, for which the wave function is a solution as discussed in Section 41.3.

6We shall show this result explicitly in Section 41.3.
The wave functions $\psi_n$ for a particle in a box with $n = 1, 2, \text{and } 3$

The probability densities $|\psi_n|^2$ for a particle in a box with $n = 1, 2, \text{and } 3$

Normalizing this wave function shows that $A = \sqrt{2/L}$. (See Problem 18.) Therefore, the normalized wave function for the particle in a box is

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin \left( \frac{n\pi x}{L} \right)$$  \hspace{1cm} (41.13)

Figures 41.4a and b are graphical representations of $\psi_n$ versus $x$ and $|\psi_n|^2$ versus $x$ for $n = 1, 2, \text{and } 3$ for the particle in a box. Although a general wave function $\psi$ can have positive and negative values, $|\psi|^2$ is always positive. Because $|\psi|^2$ represents a probability density, a negative value for $|\psi|^2$ would be meaningless.

Further inspection of Figure 41.4b shows that $|\psi|^2$ is zero at the boundaries, satisfying our boundary conditions. In addition, $|\psi|^2$ is zero at other points, depending on the value of $n$. For $n = 2$, $|\psi_2|^2 = 0$ at $x = L/2$; for $n = 3$, $|\psi_3|^2 = 0$ at $x = L/3$ and at $x = 2L/3$. The number of zero points increases by one each time the quantum number increases by one.

Because the wavelengths of the particle are restricted by the condition $\lambda = 2L/n$, the magnitude of the momentum of the particle is also restricted to specific values, which can be found from the expression for the de Broglie wavelength, Equation 40.17:

$$p = \frac{\hbar}{\lambda} = \frac{\hbar}{2L/n} = \frac{nh}{2L} \hspace{1cm} (41.14)$$

We have chosen the potential energy of the system to be zero when the particle is inside the box. Therefore, the energy of the system is simply the kinetic energy of the particle and the allowed values are given by

$$E_n = \frac{1}{2}mu^2 = \frac{p^2}{2m} = \frac{(nh/2L)^2}{2m}$$

$$E_n = \left( \frac{\hbar^2}{8mL^2} \right) n^2 \hspace{1cm} n = 1, 2, 3, \ldots$$

This expression shows that the energy of the particle is quantized. The lowest allowed energy corresponds to the ground state, which is the lowest energy state for any system. For the particle in a box, the ground state corresponds to $n = 1$, for which $E_1 = \hbar^2/8mL^2$. Because $E_n = n^2E_1$, the excited states corresponding to $n = 2, 3, 4, \ldots$ have energies given by $4E_1, 9E_1, 16E_1, \ldots$.

**Pitfall Prevention 41.1**

Reminder: Energy Belongs to a System We often refer to the energy of a particle in commonly used language. As in Pitfall Prevention 41.1, we are actually describing the energy of the system of the particle and whatever environment is establishing the impenetrable walls. For the particle in a box, the only type of energy is kinetic energy belonging to the particle, which is the origin of the common description.

**Note**: that $n = 0$ is not allowed because, according to Equation 41.12, the wave function would be $\psi = 0$, which is not a physically reasonable wave function. For example, it cannot be normalized because $\int_{-L}^{L} |\psi|^2 dx = \int_{-L}^{L} (0) dx = 0$, but Equation 41.7 tells us that this integral must equal 1.
Figure 41.5 is an energy-level diagram describing the energy values of the allowed states. Because the lowest energy of the particle in a box is not zero, then, according to quantum mechanics, the particle can never be at rest! The smallest energy it can have, corresponding to \( n = 1 \), is called the \textit{ground-state energy}. This result contradicts the classical viewpoint, in which \( E = 0 \) is an acceptable state, as are \textit{all} positive values of \( E \).

\textbf{Quick Quiz 41.2} Consider an electron, a proton, and an alpha particle (a helium nucleus), each trapped separately in identical boxes. 

(i) Which particle corresponds to the highest ground-state energy? (a) the electron (b) the proton (c) the alpha particle (d) The ground-state energy is the same in all three cases.

(ii) Which particle has the longest wavelength when the system is in the ground state? (a) the electron (b) the proton (c) the alpha particle (d) All three particles have the same wavelength.

\textbf{Quick Quiz 41.3} A particle is in a box of length \( L \). Suddenly, the length of the box is increased to \( 2L \). What happens to the energy levels shown in Figure 41.5? (a) nothing; they are unaffected. (b) They move farther apart. (c) They move closer together.

\textbf{Example 41.2} \hspace{1cm} \textbf{Microscopic and Macroscopic Particles in Boxes}

\textbf{(A)} An electron is confined between two impenetrable walls 0.200 nm apart. Determine the energy levels for the states \( n = 1, 2, \) and 3.

\section*{Solution}

\textbf{Conceptualize} \hspace{1cm} In Figure 41.3a, imagine that the particle is an electron and the walls are very close together.

\textbf{Categorize} \hspace{1cm} We evaluate the energy levels using an equation developed in this section, so we categorize this example as a substitution problem.

Use Equation 41.14 for the \( n = 1 \) state:

\[ E_1 = \frac{\hbar^2}{8mL^2}(1)^2 = \frac{(6.63 \times 10^{-34} \text{ J} \cdot \text{s})^2}{8(9.11 \times 10^{-31} \text{ kg})(2.00 \times 10^{-10} \text{ m})^2} = 1.51 \times 10^{-18} \text{ J} = 9.42 \text{ eV} \]

Using \( E_n = n^2E_1 \), find the energies of the \( n = 2 \) and \( n = 3 \) states:

\[ E_2 = (2)^2E_1 = 4(9.42 \text{ eV}) = 37.7 \text{ eV} \]

\[ E_3 = (3)^2E_1 = 9(9.42 \text{ eV}) = 84.8 \text{ eV} \]

\textbf{(B)} Find the speed of the electron in the \( n = 1 \) state.

\section*{Solution}

Solve the classical expression for kinetic energy for the particle speed:

\[ K = \frac{1}{2}m_eu^2 \rightarrow u = \sqrt{\frac{2K}{m_e}} \]

Recognize that the kinetic energy of the particle is equal to the system energy and substitute \( E_n \) for \( K \):

\[ u = \sqrt{\frac{2E_n}{m_e}} \]

Substitute numerical values from part (A):

\[ u = \sqrt{\frac{2(1.51 \times 10^{-18} \text{ J})}{9.11 \times 10^{-31} \text{ kg}}} = 1.82 \times 10^6 \text{ m/s} \]

Simply placing the electron in the box results in a \textit{minimum} speed of the electron equal to 0.6% of the speed of light!

\textbf{(C)} A 0.500-kg baseball is confined between two rigid walls of a stadium that can be modeled as a box of length 100 m. Calculate the minimum speed of the baseball.
41.2 continued

**Solution**

**Conceptualize** In Figure 41.3a, imagine that the particle is a baseball and the walls are those of the stadium.

**Categorize** This part of the example is a substitution problem in which we apply a quantum approach to a macroscopic object.

Use Equation 41.14 for the \( n = 1 \) state:

\[
E_1 = \frac{\hbar^2}{8mL^2} (2)^2 = \frac{(6.63 \times 10^{-34} \text{ J} \cdot \text{s})^2}{8(0.500 \text{ kg})(100 \text{ m})^2} = 1.10 \times 10^{-71} \text{ J}
\]

Use Equation (1) to find the speed:

\[
u = \sqrt{\frac{2E_1}{m}} = \sqrt{\frac{2(1.10 \times 10^{-71} \text{ J})}{0.500 \text{ kg}}} = 6.63 \times 10^{-35} \text{ m/s}
\]

This speed is so small that the object can be considered to be at rest, which is what one would expect for the minimum speed of a macroscopic object.

**What If?** What if a sharp line drive is hit so that the baseball is moving with a speed of 150 m/s? What is the quantum number of the state in which the baseball now resides?

**Answer** We expect the quantum number to be very large because the baseball is a macroscopic object.

Evaluate the kinetic energy of the baseball:

\[
\frac{1}{2}mu^2 = \frac{1}{2}(0.500 \text{ kg})(150 \text{ m/s})^2 = 5.62 \times 10^5 \text{ J}
\]

From Equation 41.14, calculate the quantum number \( n \):

\[
n = \sqrt{\frac{8mL^2E_n}{\hbar^2}} = \sqrt{\frac{8(0.500 \text{ kg})(100 \text{ m})^2(5.62 \times 10^5 \text{ J})}{(6.63 \times 10^{-34} \text{ J} \cdot \text{s})^2}} = 2.26 \times 10^{37}
\]

This result is a tremendously large quantum number. As the baseball pushes air out of the way, hits the ground, and rolls to a stop, it moves through more than \( 10^{37} \) quantum states. These states are so close together in energy that we cannot observe the transitions from one state to the next. Rather, we see what appears to be a smooth variation in the speed of the ball. The quantum nature of the universe is simply not evident in the motion of macroscopic objects.

---

**Example 41.3** The Expectation Values for the Particle in a Box

A particle of mass \( m \) is confined to a one-dimensional box between \( x = 0 \) and \( x = L \). Find the expectation value of the position \( x \) of the particle in the state characterized by quantum number \( n \).

**Solution**

**Conceptualize** Figure 41.4b shows that the probability for the particle to be at a given location varies with position within the box. Can you predict what the expectation value of \( x \) will be from the symmetry of the wave functions?

**Categorize** The statement of the example categorizes the problem for us: we focus on a quantum particle in a box and on the calculation of its expectation value of \( x \).

**Analyze** In Equation 41.8, the integration from \( -\infty \) to \( \infty \) reduces to the limits 0 to \( L \) because \( \psi = 0 \) everywhere except in the box.

Substitute Equation 41.13 into Equation 41.8 to find the expectation value for \( x \):

\[
\langle x \rangle = \int_{-\infty}^{\infty} \psi_\alpha^* x \psi_\alpha \, dx = \int_0^L x \left[ \sqrt{\frac{2}{L}} \sin \left( \frac{n\pi x}{L} \right) \right]^2 \, dx
\]

\[
= \frac{2}{L} \int_0^L x \sin^2 \left( \frac{n\pi x}{L} \right) \, dx
\]

*continued*
Evaluate the integral by consulting an integral table or by mathematical integration:

\[
\langle x \rangle = \frac{2}{L} \left[ \frac{x^2}{4} - \frac{x \sin \left( \frac{2n\pi x}{L} \right)}{4} - \frac{\cos \left( \frac{2n\pi x}{L} \right)}{8\left( \frac{n\pi}{L} \right)^2} \right]_0^L
\]

\[
= \frac{2}{L} \left[ \frac{L^2}{4} \right] = \frac{L}{2}
\]

**Finalize** This result shows that the expectation value of \( x \) is at the center of the box for all values of \( n \), which you would expect from the symmetry of the square of the wave functions (the probability density) about the center (Fig. 41.4b).

The \( n = 2 \) wave function in Figure 41.4b has a value of zero at the midpoint of the box. Can the expectation value of the particle be at a position at which the particle has zero probability of existing? Remember that the expectation value is the *average* position. Therefore, the particle is as likely to be found to the right of the midpoint as to the left, so its average position is at the midpoint even though its probability of being there is zero. As an analogy, consider a group of students for whom the average final examination score is 50%. There is no requirement that some student achieve a score of exactly 50% for the average of all students to be 50%.

**Boundary Conditions on Particles in General**

The discussion of the particle in a box is very similar to the discussion in Chapter 18 of standing waves on strings:

- Because the ends of the string must be nodes, the wave functions for allowed waves must be zero at the boundaries of the string. Because the particle in a box cannot exist outside the box, the allowed wave functions for the particle must be zero at the boundaries.
- The boundary conditions on the string waves lead to quantized wavelengths and frequencies of the waves. The boundary conditions on the wave function for the particle in a box lead to quantized wavelengths and frequencies of the particle.

In quantum mechanics, it is very common for particles to be subject to boundary conditions. We therefore introduce a new analysis model, the **quantum particle under boundary conditions**. In many ways, this model is similar to the waves under boundary conditions model studied in Section 18.3. In fact, the allowed wavelengths for the wave function of a particle in a box (Eq. 41.11) are identical in form to the allowed wavelengths for mechanical waves on a string fixed at both ends (Eq. 18.4).

The quantum particle under boundary conditions model **differs** in some ways from the waves under boundary conditions model:

- In most cases of quantum particles, the wave function is *not* a simple sinusoidal function like the wave function for waves on strings. Furthermore, the wave function for a quantum particle may be a complex function.
- For a quantum particle, frequency is related to energy through \( E = hf \), so the quantized frequencies lead to quantized energies.
- There may be no stationary “nodes” associated with the wave function of a quantum particle under boundary conditions. Systems more complicated than the particle in a box have more complicated wave functions, and some boundary conditions may not lead to zeroes of the wave function at fixed points.

---

To integrate this function, first replace \( \sin^2 \left( \frac{n\pi x}{L} \right) \) with \( \frac{1}{2} \left( 1 - \cos 2n\pi x/L \right) \) (refer to Table B.3 in Appendix B), which allows \( \langle x \rangle \) to be expressed as two integrals. The second integral can then be evaluated by partial integration (Section B.7 in Appendix B).

---

**41.3 continued**

Evaluate the integral by consulting an integral table or by mathematical integration:

\[
\langle x \rangle = \frac{2}{L} \left[ \frac{x^2}{4} - \frac{x \sin \left( \frac{2n\pi x}{L} \right)}{4} - \frac{\cos \left( \frac{2n\pi x}{L} \right)}{8\left( \frac{n\pi}{L} \right)^2} \right]_0^L
\]

\[
= \frac{2}{L} \left[ \frac{L^2}{4} \right] = \frac{L}{2}
\]
In general, an interaction of a quantum particle with its environment represents one or more boundary conditions, and, if the interaction restricts the particle to a finite region of space, results in quantization of the energy of the system.

Boundary conditions on quantum wave functions are related to the coordinates describing the problem. For the particle in a box, the wave function must be zero at two values of \( x \). In the case of a three-dimensional system such as the hydrogen atom we shall discuss in Chapter 42, the problem is best presented in spherical coordinates. These coordinates, an extension of the plane polar coordinates introduced in Section 3.1, consist of a radial coordinate \( r \) and two angular coordinates. The generation of the wave function and application of the boundary conditions for the hydrogen atom are beyond the scope of this book. We shall, however, examine the behavior of some of the hydrogen-atom wave functions in Chapter 42.

Boundary conditions on wave functions that exist for all values of \( x \) require that the wave function approach zero as \( x \to \infty \) (so that the wave function can be normalized) and remain finite as \( x \to 0 \). One boundary condition on any angular parts of wave functions is that adding \( 2\pi \) radians to the angle must return the wave function to the same value because an addition of \( 2\pi \) results in the same angular position.

**Analysis Model**

**Quantum Particle Under Boundary Conditions**

Imagine a particle described by quantum physics that is subject to one or more boundary conditions. If the particle is restricted to a finite region of space by the boundary conditions, the energy of the system is quantized. Associated with each quantized energy is a quantum state characterized by a wave function and a quantum number.

**Examples:**
- an electron in a quantum dot cannot escape, quantizing the energies of the electron (Section 41.4)
- an electron in a hydrogen atom is restricted to stay near the nucleus of the atom, quantizing the energies of the atom (Chapter 42)
- two atoms are bound to form a diatomic molecule, quantizing the energies of vibration and rotation of the molecule (Chapter 43)
- a proton is trapped in a nucleus, quantizing its energy levels (Chapter 44)

### 41.3 The Schrödinger Equation

In Section 34.3, we discussed a linear wave equation for electromagnetic radiation that follows from Maxwell’s equations. The waves associated with particles also satisfy a wave equation. The wave equation for material particles is different from that associated with photons because material particles have a nonzero rest energy. The appropriate wave equation was developed by Schrödinger in 1926. In analyzing the behavior of a quantum system, the approach is to determine a solution to this equation and then apply the appropriate boundary conditions to the solution. This process yields the allowed wave functions and energy levels of the system under consideration. Proper manipulation of the wave function then enables one to calculate all measurable features of the system.

The Schrödinger equation as it applies to a particle of mass \( m \) confined to moving along the \( x \) axis and interacting with its environment through a potential energy function \( U(x) \) is

\[
\frac{-\hbar^2}{2m} \frac{d^2\psi}{dx^2} + U\psi = E\psi
\]  

(41.15)  

Time-independent Schrödinger equation
where $E$ is a constant equal to the total energy of the system (the particle and its environment). Because this equation is independent of time, it is commonly referred to as the **time-independent Schrödinger equation**. (We shall not discuss the time-dependent Schrödinger equation in this book.)

The Schrödinger equation is consistent with the principle of conservation of mechanical energy for an isolated system with no nonconservative forces acting. Problem 44 shows, both for a free particle and a particle in a box, that the first term in the Schrödinger equation reduces to the kinetic energy of the particle multiplied by the wave function. Therefore, Equation 41.15 indicates that the total energy of the system is the sum of the kinetic energy and the potential energy and that the total energy is a constant: $K + U = E = \text{constant}$.

In principle, if the potential energy function $U$ for a system is known, one can solve Equation 41.15 and obtain the wave functions and energies for the allowed states of the system. In addition, in many cases, the wave function $\psi$ must satisfy boundary conditions. Therefore, once we have a preliminary solution to the Schrödinger equation, we impose the following conditions to find the exact solution and the allowed energies:

- $\psi$ must be normalizable. That is, Equation 41.7 must be satisfied.
- $\psi$ must go to 0 as $x \to \pm \infty$ and remain finite as $x \to 0$.
- $\psi$ must be continuous in $x$ and be single-valued everywhere; solutions to Equation 41.15 in different regions must join smoothly at the boundaries between the regions.
- $d\psi/dx$ must be finite, continuous, and single-valued everywhere for finite values of $U$. If $d\psi/dx$ were not continuous, we would not be able to evaluate the second derivative $d^2\psi/dx^2$ in Equation 41.15 at the point of discontinuity.

The task of solving the Schrödinger equation may be very difficult, depending on the form of the potential energy function. As it turns out, the Schrödinger equation is extremely successful in explaining the behavior of atomic and nuclear systems, whereas classical physics fails to explain this behavior. Furthermore, when quantum mechanics is applied to macroscopic objects, the results agree with classical physics.

**The Particle in a Box Revisited**

To see how the quantum particle under boundary conditions model is applied to a problem, let’s return to our particle in a one-dimensional box of length $L$ (see Fig. 41.3) and analyze it with the Schrödinger equation. Figure 41.3b is the potential-energy diagram that describes this problem. Potential-energy diagrams are a useful representation for understanding and solving problems with the Schrödinger equation.

Because of the shape of the curve in Figure 41.3b, the particle in a box is sometimes said to be in a **square well**, where a well is an upward-facing region of the curve in a potential-energy diagram. (A downward-facing region is called a barrier, which we investigate in Section 41.5.) Figure 41.3b shows an infinite square well.

In the region $0 < x < L$, where $U = 0$, we can express the Schrödinger equation in the form

$$
\frac{d^2\psi}{dx^2} = -\frac{2mE}{\hbar^2} \psi = -k^2 \psi
$$

where

$$
k = \frac{\sqrt{2mE}}{\hbar}
$$

It is called a square well even if it has a rectangular shape in a potential-energy diagram.
The solution to Equation 41.16 is a function $\psi$ whose second derivative is the negative of the same function multiplied by a constant $k^2$. Both the sine and cosine functions satisfy this requirement. Therefore, the most general solution to the equation is a linear combination of both solutions:

$$\psi(x) = A \sin kx + B \cos kx$$

where $A$ and $B$ are constants that are determined by the boundary and normalization conditions.

The first boundary condition on the wave function is that $\psi(0) = 0$:

$$\psi(0) = A \sin 0 + B \cos 0 = 0 + B = 0$$

which means that $B = 0$. Therefore, our solution reduces to

$$\psi(x) = A \sin kx$$

The second boundary condition, $\psi(L) = 0$, when applied to the reduced solution gives

$$\psi(L) = A \sin kL = 0$$

This equation could be satisfied by setting $A = 0$, but that would mean that $\psi = 0$ everywhere, which is not a valid wave function. The boundary condition is also satisfied if $kL$ is an integral multiple of $\pi$, that is, if $kL = n\pi$, where $n$ is an integer. Substituting $k = \sqrt{2mE}/\hbar$ into this expression gives

$$kL = \frac{\sqrt{2mE}}{\hbar} L = n\pi$$

Each value of the integer $n$ corresponds to a quantized energy that we call $E_n$. Solving for the allowed energies $E_n$ gives

$$E_n = \left(\frac{k^2}{8mL^2}\right)n^2$$

which are identical to the allowed energies in Equation 41.14. Substituting the values of $k$ in the wave function, the allowed wave functions $\psi_n(x)$ are given by

$$\psi_n(x) = A \sin \left(\frac{n\pi x}{L}\right)$$

which is the wave function (Eq. 41.12) used in our initial discussion of the particle in a box.

### 41.4 A Particle in a Well of Finite Height

Now consider a particle in a finite potential well, that is, a system having a potential energy that is zero when the particle is in the region $0 < x < L$ and a finite value $U$ when the particle is outside this region as in Figure 41.6. Classically, if the total energy $E$ of the system is less than $U$, the particle is permanently bound in the potential well. If the particle were outside the well, its kinetic energy would have to be negative, which is an impossibility. According to quantum mechanics, however, a finite probability exists that the particle can be found outside the well even if $E < U$. That is, the wave function $\psi$ is generally nonzero outside the well—regions I and III in Figure 41.6—so the probability density $|\psi|^2$ is also nonzero in these regions. Although this notion may be uncomfortable to accept, the uncertainty principle indicates that the energy of the system is uncertain. This uncertainty allows the particle to be outside the well as long as the apparent violation of conservation of energy does not exist in any measurable way.

In region II, where $U = 0$, the allowed wave functions are again sinusoidal because they represent solutions of Equation 41.16. The boundary conditions, however,
The wave functions $\phi_n$ for a particle in a potential well of finite height with $n = 1, 2, \text{and } 3$

The probability densities $|\phi_n|^2$ for a particle in a potential well of finite height with $n = 1, 2, \text{and } 3$

**Figure 41.7** The first three allowed states for a particle in a potential well of finite height. The states are shown superimposed on the potential energy function of Figure 41.6. The wave functions and probability densities are plotted vertically from separate axes that are offset vertically for clarity. The positions of these axes on the potential energy function suggest the relative energies of the states.

no longer require that $\psi$ be zero at the ends of the well, as was the case with the infinite square well.

The Schrödinger equation for regions I and III may be written

$$\frac{d^2\psi}{dx^2} = \frac{2m(U - E)}{\hbar^2} \psi$$  \hspace{1cm} (41.19)

Because $U > E$, the coefficient of $\psi$ on the right-hand side is necessarily positive. Therefore, we can express Equation 41.19 as

$$\frac{d^2\psi}{dx^2} = C^2\psi$$  \hspace{1cm} (41.20)

where $C^2 = 2m(U - E)/\hbar^2$ is a positive constant in regions I and III. As you can verify by substitution, the general solution of Equation 41.20 is

$$\psi = Ae^{Cx} + Be^{-Cx}$$  \hspace{1cm} (41.21)

where $A$ and $B$ are constants.

We can use this general solution as a starting point for determining the appropriate solution for regions I and III. The solution must remain finite as $x \to \pm \infty$. Therefore, in region I, where $x < 0$, the function $\psi$ cannot contain the term $Be^{-Cx}$.

This requirement is handled by taking $B = 0$ in this region to avoid an infinite value for $\psi$ for large negative values of $x$. Likewise, in region III, where $x > L$, the function $\psi$ cannot contain the term $Ae^{Cx}$. This requirement is handled by taking $A = 0$ in this region to avoid an infinite value for $\psi$ for large positive $x$ values.

Hence, the solutions in regions I and III are

$$\psi_1 = Ae^{Cx} \quad \text{for } x < 0$$
$$\psi_{\text{II}} = Be^{-Cx} \quad \text{for } x > L$$

In region II, the wave function is sinusoidal and has the general form

$$\psi_{\text{II}}(x) = F \sin (kx) + G \cos (kx)$$

where $F$ and $G$ are constants.

These results show that the wave functions outside the potential well (where classical physics forbids the presence of the particle) decay exponentially with distance. At large negative $x$ values, $\psi_1$ approaches zero; at large positive $x$ values, $\psi_{\text{II}}$ approaches zero. These functions, together with the sinusoidal solution in region II, are shown in Figure 41.7a for the first three energy states. In evaluating the complete wave function, we impose the following boundary conditions:

$$\psi_1 = \psi_{\text{II}} \quad \text{and} \quad \frac{d\psi_1}{dx} = \frac{d\psi_{\text{II}}}{dx} \quad \text{at } x = 0$$

$$\psi_{\text{II}} = \psi_{\text{III}} \quad \text{and} \quad \frac{d\psi_{\text{II}}}{dx} = \frac{d\psi_{\text{III}}}{dx} \quad \text{at } x = L$$

These four boundary conditions and the normalization condition (Eq. 41.7) are sufficient to determine the four constants $A$, $B$, $F$, and $G$ and the allowed values of the energy $E$. Figure 41.7b plots the probability densities for these states. In each case, the wave functions inside and outside the potential well join smoothly at the boundaries.

The notion of trapping particles in potential wells is used in the burgeoning field of nanotechnology, which refers to the design and application of devices having dimensions ranging from 1 to 100 nm. The fabrication of these devices often involves manipulating single atoms or small groups of atoms to form very tiny structures or mechanisms.

One area of nanotechnology of interest to researchers is the quantum dot, a small region that is grown in a silicon crystal and acts as a potential well. This region can trap electrons into states with quantized energies. The wave functions...
for a particle in a quantum dot look similar to those in Figure 41.7a if $L$ is on the order of nanometers. The storage of binary information using quantum dots is an active field of research. A simple binary scheme would involve associating a one with a quantum dot containing an electron and a zero with an empty dot. Other schemes involve cells of multiple dots such that arrangements of electrons among the dots correspond to ones and zeroes. Several research laboratories are studying the properties and potential applications of quantum dots. Information should be forthcoming from these laboratories at a steady rate in the next few years.

### 41.5 Tunneling Through a Potential Energy Barrier

Consider the potential energy function shown in Figure 41.8. In this situation, the potential energy has a constant value of $U$ in the region of width $L$ and is zero in all other regions. A potential energy function of this shape is called a square barrier, and $U$ is called the barrier height. A very interesting and peculiar phenomenon occurs when a moving particle encounters such a barrier of finite height and width. Suppose a particle of energy $E < U$ is incident on the barrier from the left (Fig. 41.8). Classically, the particle is reflected by the barrier. If the particle were located in region II, its kinetic energy would be negative, which is not classically allowed. Consequently, region II and therefore region III are both classically forbidden to the particle incident from the left. According to quantum mechanics, however, all regions are accessible to the particle, regardless of its energy. (Although all regions are accessible, the probability of the particle being in a classically forbidden region is very low.) According to the uncertainty principle, the particle could be within the barrier as long as the time interval during which it is in the barrier is short and consistent with Equation 40.26. If the barrier is relatively narrow, this short time interval can allow the particle to pass through the barrier.

Let’s approach this situation using a mathematical representation. The Schrödinger equation has valid solutions in all three regions. The solutions in regions I and III are sinusoidal like Equation 41.18. In region II, the solution is exponential like Equation 41.21. Applying the boundary conditions that the wave functions and their derivatives must join smoothly at the boundaries, a full solution, such as the one represented by the curve in Figure 41.8, can be found. Because the probability of locating the particle is proportional to $|\psi|^2$, the probability of finding the particle beyond the barrier in region III is nonzero. This result is in complete disagreement with classical physics. The movement of the particle to the far side of the barrier is called tunneling or barrier penetration.

The probability of tunneling can be described with a transmission coefficient $T$ and a reflection coefficient $R$. The transmission coefficient represents the probability that the particle penetrates to the other side of the barrier, and the reflection coefficient is the probability that the particle is reflected by the barrier. Because the incident particle is either reflected or transmitted, we require that $T + R = 1$. An approximate expression for the transmission coefficient that is obtained in the case of $T << 1$ (a very wide barrier or a very high barrier, that is, $U >> E$) is

$$T \approx e^{-2CL} \tag{41.22}$$

where

$$C = \frac{\sqrt{2m(U - E)}}{h} \tag{41.23}$$

This quantum model of barrier penetration and specifically Equation 41.22 show that $T$ can be nonzero. That the phenomenon of tunneling is observed experimentally provides further confidence in the principles of quantum physics.

---

It is common in physics to refer to $L$ as the length of a well but the width of a barrier.

---

**Pitfall Prevention 41.4**

"Height" on an Energy Diagram The word height (as in barrier height) refers to an energy in discussions of barriers in potential-energy diagrams. For example, we might say the height of the barrier is 10 eV. On the other hand, the barrier width refers to the traditional usage of such a word and is an actual physical length measurement between the locations of the two vertical sides of the barrier.
Quick Quiz 41.4 Which of the following changes would increase the probability of transmission of a particle through a potential barrier? (You may choose more than one answer.) (a) decreasing the width of the barrier (b) increasing the width of the barrier (c) decreasing the height of the barrier (d) increasing the height of the barrier (e) decreasing the kinetic energy of the incident particle (f) increasing the kinetic energy of the incident particle.

Example 41.4 Transmission Coefficient for an Electron

A 30-eV electron is incident on a square barrier of height 40 eV.

(A) What is the probability that the electron tunnels through the barrier if its width is 1.0 nm?

Solution

Conceptualize Because the particle energy is smaller than the height of the potential barrier, we expect the electron to reflect from the barrier with a probability of 100% according to classical physics. Because of the tunneling phenomenon, however, there is a finite probability that the particle can appear on the other side of the barrier.

Categorize We evaluate the probability using an equation developed in this section, so we categorize this example as a substitution problem.

Evaluate the quantity \( U - E \) that appears in Equation 41.23:

\[
U - E = 40 \text{ eV} - 30 \text{ eV} = 10 \text{ eV} \left( \frac{1.6 \times 10^{-19} \text{ J}}{1 \text{ eV}} \right) = 1.6 \times 10^{-18} \text{ J}
\]

Evaluate the quantity \( 2CL \) using Equation 41.23:

\[
2CL = 2 \sqrt{\frac{2(9.11 \times 10^{-31} \text{ kg})(1.6 \times 10^{-18} \text{ J})}{1.055 \times 10^{-34} \text{ J} \cdot \text{s}}} \left( 1.0 \times 10^{-9} \text{ m} \right) = 32.4
\]

From Equation 41.22, find the probability of tunneling through the barrier:

\[
T = e^{-2CL} = e^{-32.4} = 8.5 \times 10^{-15}
\]

(B) What is the probability that the electron tunnels through the barrier if its width is 0.10 nm?

Solution

In this case, the width \( L \) in Equation (1) is one-tenth as large, so evaluate the new value of \( 2CL \):

\[
2CL = (0.1)(32.4) = 3.24
\]

From Equation 41.22, find the new probability of tunneling through the barrier:

\[
T = e^{-2CL} = e^{-3.24} = 0.039
\]

In part (A), the electron has approximately 1 chance in \( 10^{14} \) of tunneling through the barrier. In part (B), however, the electron has a much higher probability (3.9%) of penetrating the barrier. Therefore, reducing the width of the barrier by only one order of magnitude increases the probability of tunneling by about 12 orders of magnitude!

41.6 Applications of Tunneling

As we have seen, tunneling is a quantum phenomenon, a manifestation of the wave nature of matter. Many examples exist (on the atomic and nuclear scales) for which tunneling is very important.

Alpha Decay

One form of radioactive decay is the emission of alpha particles (the nuclei of helium atoms) by unstable, heavy nuclei (Chapter 44). To escape from the nucleus, an alpha particle must penetrate a barrier whose height is several times larger than
the energy of the nucleus–alpha particle system as shown in Figure 41.9. The barrier results from a combination of the attractive nuclear force (discussed in Chapter 44) and the Coulomb repulsion (discussed in Chapter 23) between the alpha particle and the rest of the nucleus. Occasionally, an alpha particle tunnels through the barrier, which explains the basic mechanism for this type of decay and the large variations in the mean lifetimes of various radioactive nuclei.

Figure 41.8 shows the wave function of a particle tunneling through a barrier in one dimension. A similar wave function having spherical symmetry describes the barrier penetration of an alpha particle leaving a radioactive nucleus. The wave function exists both inside and outside the nucleus, and its amplitude is constant in time. In this way, the wave function correctly describes the small but constant probability that the nucleus will decay. The moment of decay cannot be predicted. In general, quantum mechanics implies that the future is indeterminate. This feature is in contrast to classical mechanics, from which the trajectory of an object can be calculated to arbitrarily high precision from precise knowledge of its initial position and velocity and of the forces exerted on it. Do not think that the future is undetermined simply because we have incomplete information about the present. The wave function contains all the information about the state of a system. Sometimes precise predictions can be made, such as the energy of a bound system, but sometimes only probabilities can be calculated about the future. The fundamental laws of nature are probabilistic. Therefore, it appears that Einstein’s famous statement about quantum mechanics, “God does not roll dice,” was wrong.

A radiation detector can be used to show that a nucleus decays by emitting a particle at a particular moment and in a particular direction. To point out the contrast between this experimental result and the wave function describing it, Schrödinger imagined a box containing a cat, a radioactive sample, a radiation counter, and a vial of poison. When a nucleus in the sample decays, the counter triggers the administration of lethal poison to the cat. Quantum mechanics correctly predicts the probability of finding the cat dead when the box is opened. Before the box is opened, does the cat have a wave function describing it as fractionally dead, with some chance of being alive?

This question is under continuing investigation, never with actual cats but sometimes with interference experiments building upon the experiment described in Section 40.7. Does the act of measurement change the system from a probabilistic to a definite state? When a particle emitted by a radioactive nucleus is detected at one particular location, does the wave function describing the particle drop instantaneously to zero everywhere else in the Universe? (Einstein called such a state change a “spooky action at a distance.”) Is there a fundamental difference between a quantum system and a macroscopic system? The answers to these questions are unknown.

**Nuclear Fusion**

The basic reaction that powers the Sun and, indirectly, almost everything else in the solar system is fusion, which we shall study in Chapter 45. In one step of the process that occurs at the core of the Sun, protons must approach one another to within such a small distance that they fuse and form a deuterium nucleus. (See Section 45.4.) According to classical physics, these protons cannot overcome and penetrate the barrier caused by their mutual electrical repulsion. Quantum mechanically, however, the protons are able to tunnel through the barrier and fuse together.

**Scanning Tunneling Microscopes**

The scanning tunneling microscope (STM) enables scientists to obtain highly detailed images of surfaces at resolutions comparable to the size of a single atom. Figure 41.10 (page 1284), showing the surface of a piece of graphite, demonstrates what STMs can do. What makes this image so remarkable is that its resolution is
approximately 0.2 nm. For an optical microscope, the resolution is limited by the wavelength of the light used to make the image. Therefore, an optical microscope has a resolution no better than 200 nm, about half the wavelength of visible light, and so could never show the detail displayed in Figure 41.10.

Scanning tunneling microscopes achieve such high resolution by using the basic idea shown in Figure 41.11. An electrically conducting probe with a very sharp tip is brought near the surface to be studied. The empty space between tip and surface represents the “barrier” we have been discussing, and the tip and surface are the two walls of the “potential well.” Because electrons obey quantum rules rather than Newtonian rules, they can “tunnel” across the barrier of empty space. If a voltage is applied between surface and tip, electrons in the atoms of the surface material can tunnel preferentially from surface to tip to produce a tunneling current. In this way, the tip samples the distribution of electrons immediately above the surface.

In the empty space between tip and surface, the electron wave function falls off exponentially (see region II in Fig. 41.8 and Example 41.4). For tip-to-surface distances \( z \geq 1 \text{ nm} \) (that is, beyond a few atomic diameters), essentially no tunneling takes place. This exponential behavior causes the current of electrons tunneling from surface to tip to depend very strongly on \( z \).

By monitoring the tunneling current as the tip is scanned over the surface, scientists obtain a sensitive measure of the topography of the electron distribution on the surface. The result of this scan is used to make images like that in Figure 41.10.

In this way, the STM can measure the height of surface features to within 0.001 nm, approximately 1/100 of an atomic diameter!

You can appreciate the sensitivity of STMs by examining Figure 41.10. Of the six carbon atoms in each ring, three appear lower than the other three. In fact, all six atoms are at the same height, but all have slightly different electron distributions. The three atoms that appear lower are bonded to other carbon atoms directly beneath them in the underlying atomic layer; as a result, their electron distributions, which are responsible for the bonding, extend downward beneath the surface. The atoms in the surface layer that appear higher do not lie directly over subsurface atoms and hence are not bonded to any underlying atoms. For these higher-appearing atoms, the electron distribution extends upward into the space above the surface. Because STMs map the topography of the electron distribution, this extra electron density makes these atoms appear higher in Figure 41.10.

The STM has one serious limitation: Its operation depends on the electrical conductivity of the sample and the tip. Unfortunately, most materials are not electrically conductive at their surfaces. Even metals, which are usually excellent electrical conductors, are covered with nonconductive oxides. A newer microscope, the atomic force microscope, or AFM, overcomes this limitation.

**Resonant Tunneling Devices**

Let’s expand on the quantum-dot discussion in Section 41.4 by exploring the **resonant tunneling device**. Figure 41.12a shows the physical construction of such a device. The island of gallium arsenide in the center is a quantum dot located between two barriers formed from the thin extensions of aluminum arsenide. Figure 41.12b shows both the potential barriers encountered by electrons incident from the left and the quantized energy levels in the quantum dot. This situation differs from the one shown in Figure 41.8 in that there are quantized energy levels on the right of the first barrier. In Figure 41.8, an electron that tunnels through the barrier is considered a free particle and can have any energy. In contrast, the second barrier in Figure 41.12b imposes boundary conditions on the particle and quantizes its energy in the quantum dot. In Figure 41.12b, as the electron with the energy shown encounters the first barrier, it has no matching energy levels available on the right side of the barrier, which greatly reduces the probability of tunneling.
Figure 41.12c shows the effect of applying a voltage: the potential decreases with position as we move to the right across the device. The deformation of the potential barrier results in an energy level in the quantum dot coinciding with the energy of the incident electrons. This “resonance” of energies gives the device its name. When the voltage is applied, the probability of tunneling increases tremendously and the device carries current. In this manner, the device can be used as a very fast switch on a nanotechnological scale.

**Resonant Tunneling Transistors**

Figure 41.13a shows the addition of a gate electrode at the top of the resonant tunneling device over the quantum dot. This electrode turns the device into a resonant
tunneling transistor. The basic function of a transistor is amplification, converting a small varying voltage into a large varying voltage. Figure 41.13b, representing the potential-energy diagram for the tunneling transistor, has a slope at the bottom of the quantum dot due to the differing voltages at the source and drain electrodes. In this configuration, there is no resonance between the electron energies outside the quantum dot and the quantized energies within the dot. By applying a small voltage to the gate electrode as in Figure 41.13c, the quantized energies can be brought into resonance with the electron energy outside the well and resonant tunneling occurs. The resulting current causes a voltage across an external resistor that is much larger than that of the gate voltage; hence, the device amplifies the input signal to the gate electrode.

### 41.7 The Simple Harmonic Oscillator

Consider a particle that is subject to a linear restoring force $F = -kx$, where $k$ is a constant and $x$ is the position of the particle relative to equilibrium ($x = 0$). The classical description of such a situation is provided by the particle in simple harmonic motion analysis model, which was discussed in Chapter 15. The potential energy of the system is, from Equation 15.20,

$$U = \frac{1}{2} k x^2 = \frac{1}{2} m \omega^2 x^2$$

where the angular frequency of vibration is $\omega = \sqrt{k/m}$. Classically, if the particle is displaced from its equilibrium position and released, it oscillates between the points $x = -A$ and $x = A$, where $A$ is the amplitude of the motion. Furthermore, its total energy $E$ is, from Equation 15.21,

$$E = K + U = \frac{1}{2} k A^2 = \frac{1}{2} m \omega^2 A^2$$

In the classical model, any value of $E$ is allowed, including $E = 0$, which is the total energy when the particle is at rest at $x = 0$.

Let’s investigate how the simple harmonic oscillator is treated from a quantum point of view. The Schrödinger equation for this problem is obtained by substituting $U = \frac{1}{2} m \omega^2 x^2$ into Equation 41.15:

$$-\frac{\hbar^2}{2m} \frac{d^2 \psi}{dx^2} + \frac{1}{2} m \omega^2 x^2 \psi = E \psi$$  \hspace{1cm} (41.24)

The mathematical technique for solving this equation is beyond the level of this book; nonetheless, it is instructive to guess at a solution. We take as our guess the following wave function:

$$\psi = Be^{-Cx^2}$$  \hspace{1cm} (41.25)

Substituting this function into Equation 41.24 shows that it is a satisfactory solution to the Schrödinger equation, provided that

$$C = \frac{m \omega}{2\hbar} \quad \text{and} \quad E = \frac{1}{2} \hbar \omega$$

It turns out that the solution we have guessed corresponds to the ground state of the system, which has an energy $\frac{1}{2} \hbar \omega$. Because $C = m \omega / 2\hbar$, it follows from Equation 41.25 that the wave function for this state is

$$\psi = Be^{-\frac{(m \omega / 2\hbar) x^2}{2}}$$  \hspace{1cm} (41.26)

where $B$ is a constant to be determined from the normalization condition. This result is but one solution to Equation 41.24. The remaining solutions that describe the excited states are more complicated, but all solutions include the exponential factor $e^{-Cx^2}$. 
The energy levels of a harmonic oscillator are quantized as we would expect because the oscillating particle is bound to stay near \( x = 0 \). The energy of a state having an arbitrary quantum number \( n \) is

\[
E_n = (n + \frac{1}{2}) \hbar \omega \quad n = 0, 1, 2, \ldots \tag{41.27}
\]

The state \( n = 0 \) corresponds to the ground state, whose energy is \( E_0 = \frac{1}{2} \hbar \omega \); the state \( n = 1 \) corresponds to the first excited state, whose energy is \( E_1 = \frac{3}{2} \hbar \omega \); and so on. The energy-level diagram for this system is shown in Figure 41.14. The separations between adjacent levels are equal and given by

\[
\Delta E = \hbar \omega \tag{41.28}
\]

Notice that the energy levels for the harmonic oscillator in Figure 41.14 are equally spaced, just as Planck proposed for the oscillators in the walls of the cavity that was used in the model for blackbody radiation in Section 40.1. Planck's Equation 40.4 for the energy levels of the oscillators differs from Equation 41.27 only in the term \( \frac{1}{2} \) added to \( n \). This additional term does not affect the energy emitted in a transition, given by Equation 40.5, which is equivalent to Equation 41.28. That Planck generated these concepts without the benefit of the Schrödinger equation is testimony to his genius.

### Example 41.5 Molar Specific Heat of Hydrogen Gas

In Figure 21.6 (Section 21.3), which shows the molar specific heat of hydrogen as a function of temperature, vibration does not contribute to the molar specific heat at room temperature. Explain why, modeling the hydrogen molecule as a simple harmonic oscillator. The effective spring constant for the bond in the hydrogen molecule is 573 N/m.

**Solution**

**Conceptualize** Imagine the only mode of vibration available to a diatomic molecule. This mode (shown in Fig. 21.5c) consists of the two atoms always moving in opposite directions with equal speeds.

**Categorize** We categorize this example as a quantum harmonic oscillator problem, with the molecule modeled as a two-particle system.

**Analyze** The motion of the particles relative to the center of mass can be analyzed by considering the oscillation of a single particle with reduced mass \( \mu \). (See Problem 40.)

Use the result of Problem 40 to evaluate the reduced mass of the hydrogen molecule, in which the masses of the two particles are the same:

\[
\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{m^2}{2m} = \frac{1}{2} m
\]

Using Equation 41.28, calculate the energy necessary to excite the molecule from its ground vibrational state to its first excited vibrational state:

\[
\Delta E = \hbar \omega = \hbar \sqrt{\frac{k}{\mu}} = \hbar \sqrt{\frac{k}{\frac{1}{2} m}} = \hbar \sqrt{\frac{2k}{m}}
\]

Substitute numerical values, noting that \( m \) is the mass of a hydrogen atom:

\[
\Delta E = (1.055 \times 10^{-34} \text{ J} \cdot \text{s}) \sqrt{\frac{2(573 \text{ N/m})}{1.67 \times 10^{-27} \text{ kg}}} = 8.74 \times 10^{-20} \text{ J}
\]

Set this energy equal to \( \frac{3}{2} k_B T \) from Equation 21.19 and find the temperature at which the average molecular translational kinetic energy is equal to that required to excite the first vibrational state of the molecule:

\[
T = \frac{2}{3} \frac{\Delta E}{k_B} = \frac{2}{3} \left( \frac{8.74 \times 10^{-20} \text{ J}}{1.38 \times 10^{-23} \text{ J/K}} \right) = 4.22 \times 10^3 \text{ K}
\]

**Finalize** The temperature of the gas must be more than 4000 K for the translational kinetic energy to be comparable to the energy required to excite the first vibrational state. This excitation energy must come from collisions between

continued
molecules, so if the molecules do not have sufficient translational kinetic energy, they cannot be excited to the first vibrational state and vibration does not contribute to the molar specific heat. Hence, the curve in Figure 21.6 does not rise to a value corresponding to the contribution of vibration until the hydrogen gas has been raised to thousands of kelvins.

Figure 21.6 shows that rotational energy levels must be more closely spaced in energy than vibrational levels because they are excited at a lower temperature than the vibrational levels. The translational energy levels are those of a particle in a three-dimensional box, where the box is the container holding the gas. These levels are given by an expression similar to Equation 41.14. Because the box is macroscopic in size, $L$ is very large and the energy levels are very close together. In fact, they are so close together that translational energy levels are excited at the temperature at which liquid hydrogen becomes a gas shown in Figure 21.6.

### Summary

**Definitions**

- The wave function $\Psi$ for a system is a mathematical function that can be written as a product of a space function $\phi$ for one particle of the system and a complex time function:

  $$\Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \ldots, \vec{r}_j) = \phi(\vec{r}) e^{-i\omega t}$$

  where $\omega = \frac{2\pi f}{L}$ is the angular frequency of the wave function and $i = \sqrt{-1}$. The wave function contains within it all the information that can be known about the particle.

**Concepts and Principles**

- In quantum mechanics, a particle in a system can be represented by a wave function $\psi(x, y, z)$. The probability per unit volume (or probability density) that a particle will be found at a point is $|\psi|^2 = \psi^*\psi$, where $\psi^*$ is the complex conjugate of $\psi$. If the particle is confined to moving along the $x$ axis, the probability that it is located in an interval $dx$ is $|\psi|^2 dx$. Furthermore, the sum of all these probabilities over all values of $x$ must be 1:

  $$\int_{-\infty}^{\infty} |\psi|^2 dx = 1$$

  This expression is called the normalization condition.

- The measured position $x$ of a particle, averaged over many trials, is called the expectation value of $x$ and is defined by

  $$\langle x \rangle = \int_{-\infty}^{\infty} \psi^* x \psi \, dx$$

**Equations**

- The wave function for a system must satisfy the Schrödinger equation. The time-independent Schrödinger equation for a particle confined to moving along the $x$ axis is

  $$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + U\psi = E\psi$$

  where $U$ is the potential energy of the system and $E$ is the total energy.
Objective Questions

1. A beam of quantum particles with kinetic energy 2.00 eV is reflected from a potential barrier of small width and original height 3.00 eV. How does the fraction of the particles that are reflected change as the barrier height is reduced to 2.01 eV? (a) It increases. (b) It decreases. (c) It stays constant at zero. (d) It stays constant at 1. (e) It stays constant with some other value.

2. A quantum particle of mass $m_1$ is in a square well with infinitely high walls and length 3 nm. Rank the situations (a) through (e) according to the particle’s energy from highest to lowest, noting any cases of equality. (a) The particle of mass $m_1$ is in the ground state of the well. (b) The same particle is in the $n = 2$ excited state of the same well. (c) A particle with mass $2m_1$ is in the ground state of the same well. (d) A particle of mass $m_1$ in the ground state of the same well, and the uncertainty principle has become inoperative; that is, Planck’s constant has been reduced to zero. (e) A particle of mass $m_1$ is in the ground state of a well of length 6 nm.

3. Is each one of the following statements (a) through (e) true or false for an electron? (a) It is a quantum particle, behaving in some experiments like a classical particle and in some experiments like a classical wave. (b) Its rest energy is zero. (c) It carries energy in its motion. (d) It carries momentum in its motion. (e) Its motion is described by a wave function that has a wavelength and satisfies a wave equation.

4. Is each one of the following statements (a) through (e) true or false for a photon? (a) It is a quantum particle, behaving in some experiments like a classical particle and in some experiments like a classical wave. (b) Its rest energy is zero. (c) It carries energy in its motion. (d) It carries momentum in its motion. (e) Its motion is described by a wave function that has a wavelength and satisfies a wave equation.

5. A particle in a rigid box of length $L$ is in the first excited state for which $n = 2$ (Fig. OQ41.5). Where is the particle most likely to be found? (a) At the center of the box. (b) At either end of the box. (c) All points in the box are equally likely. (d) One-fourth of the way from either end of the box. (e) None of those answers is correct.

6. Two square wells have the same length. Well 1 has walls of finite height, and well 2 has walls of infinite height. Both wells contain identical quantum particles, one in each well. (i) Is the wavelength of the ground-state wave function (a) greater for well 1, (b) greater for well 2, or (c) equal for both wells? (ii) Is the magnitude of the ground-state momentum (a) greater for well 1, (b) greater for well 2, or (c) equal for both wells? (iii) Is the ground-state energy of the particle (a) greater for well 1, (b) greater for well 2, or (c) equal for both wells?

7. The probability of finding a certain quantum particle in the section of the $x$ axis between $x = 4$ nm and $x = 7$ nm is 48%. The particle’s wave function $\psi(x)$ is constant over this range. What numerical value can be attributed to $\psi(x)$, in units of nm$^{-1/2}$? (a) 0.48 (b) 0.16 (c) 0.12 (d) 0.69 (e) 0.40

8. Suppose a tunneling current in an electronic device goes through a potential-energy barrier. The tunneling current is small because the width of the barrier is large and the barrier is high. To increase the current most effectively, what should you do? (a) Reduce the width of the barrier. (b) Reduce the height of the barrier. (c) Either choice (a) or choice (b) is equally effective. (d) Neither choice (a) nor choice (b) increases the current.

9. Unlike the idealized diagram of Figure 41.11, a typical tip used for a scanning tunneling microscope is rather jagged on the atomic scale, with several irregularly spaced points. For such a tip, does most of the
tunneling current occur between the sample and (a) all the points of the tip equally, (b) the most centrally located point, (c) the point closest to the sample, or (d) the point farthest from the sample?

10. Figure OQ41.10 represents the wave function for a hypothetical quantum particle in a given region. From the choices a through e, at what value of x is the particle most likely to be found?

3. The wave function for a quantum particle is given by \( \psi(x) = A \) between \( x = 0 \) and \( x = 1.00 \), and \( \psi(x) = 0 \) elsewhere. Find (a) the value of the normalization constant \( A \), (b) the probability that the particle will be found between \( x = 0.300 \) and \( x = 0.400 \), and (c) the expectation value of the particle's position.

4. The wave function for a quantum particle is
\[
\psi(x) = \frac{a}{\pi^{1/4} (x^2 + a^2)^{3/4}}
\]
for \( a > 0 \) and \(-\infty < x < +\infty\). Determine the probability that the particle is located somewhere between \( x = -a \) and \( x = +a \).

Section 41.2 Analysis Model: Quantum Particle Under Boundary Conditions

5. (a) Use the quantum-particle-in-a-box model to calculate the first three energy levels of a neutron trapped in an atomic nucleus of diameter 20.0 fm. (b) Explain whether the energy-level differences have a realistic order of magnitude.

6. An electron that has an energy of approximately 6 eV moves between infinitely high walls 1.00 nm apart. Find (a) the quantum number \( n \) for the energy state the electron occupies and (b) the precise energy of the electron.

7. An electron is contained in a one-dimensional box of length 0.100 nm. (a) Draw an energy-level diagram for the electron for levels up to \( n = 4 \). (b) Photons are emitted by the electron making downward transitions that could eventually carry it from the \( n = 4 \) state to the \( n = 1 \) state. Find the wavelengths of all such photons.

8. Why is the following situation impossible? A proton is in an infinitely deep potential well of length 1.00 nm. It absorbs a microwave photon of wavelength 6.06 mm and is excited into the next available quantum state.

9. A ruby laser emits 694.3-nm light. Assume light of this wavelength is due to a transition of an electron in a box from its \( n = 2 \) state to its \( n = 1 \) state. Find the length of the box.

10. A laser emits light of wavelength \( \lambda \). Assume this light is due to a transition of an electron in a box from its \( n = 2 \) state to its \( n = 1 \) state. Find the length of the box.

11. The nuclear potential energy that binds protons and neutrons in a nucleus is often approximated by a square well. Imagine a proton confined in an infinitely high square well of length 10.0 fm, a typical nuclear diameter. Assuming the proton makes a transition from the \( n = 2 \) state to the ground state, calculate (a) the energy and (b) the wavelength of the emitted photon. (c) Identify the region of the electromagnetic spectrum to which this wavelength belongs.

12. A proton is confined to move in a one-dimensional box of length 0.200 nm. (a) Find the lowest possible energy of the proton. (b) What If? What is the lowest possible energy of an electron confined to the same box?

(c) How do you account for the great difference in your results for parts (a) and (b)?

13. An electron is confined to a one-dimensional region in which its ground-state \((n = 1)\) energy is 2.00 eV. (a) What is the length \( L \) of the region? (b) What energy input is required to promote the electron to its first excited state?

14. A 4.00-g particle confined to a box of length \( L \) has a speed of 1.00 mm/s. (a) What is the classical kinetic energy of the particle? (b) If the energy of the first excited state \((n = 2)\) is equal to the kinetic energy found in part (a), what is the value of \( L \)? (c) Is the result found in part (b) realistic? Explain.

15. A photon with wavelength \( \lambda \) is absorbed by an electron confined to a box. As a result, the electron moves from state \( n = 1 \) to \( n = 4 \). (a) Find the length of the box. (b) What is the wavelength \( \lambda' \) of the photon emitted in the transition of that electron from the state \( n = 4 \) to the state \( n = 2 \)?

16. For a quantum particle of mass \( m \) in the ground state of a square well with length \( L \) and infinitely high walls, the uncertainty in position is \( \Delta x \approx L \). (a) Use the uncertainty principle to estimate the uncertainty in its momentum. (b) Because the particle stays inside the box, its average momentum must be zero. Its average squared momentum is then \( \langle p^2 \rangle = (\Delta p)^2 \). Estimate the energy of the particle. (c) State how the result of part (b) compares with the actual ground-state energy.

17. A quantum particle is described by the wave function
\[
\psi(x) = \begin{cases} 
A \cos \left( \frac{2 \pi x}{L} \right) & \text{for } -\frac{L}{4} \leq x \leq \frac{L}{4} \\
0 & \text{elsewhere}
\end{cases}
\]
(a) Determine the normalization constant \( A \). (b) What is the probability that the particle will be found between \( x = 0 \) and \( x = L/4 \) if its position is measured?

18. The wave function for a quantum particle confined to moving in a one-dimensional box located between \( x = 0 \) and \( x = L \) is
\[
\psi(x) = A \sin \left( \frac{n \pi x}{L} \right)
\]
Use the normalization condition on \( \psi \) to show that
\[
A = \sqrt{\frac{2}{L}}
\]

19. A quantum particle in an infinitely deep square well has a wave function given by
\[
\psi_n(x) = \sqrt{\frac{2}{L}} \sin \left( \frac{2 \pi x}{L} \right)
\]
for \( 0 \leq x \leq L \) and zero otherwise. (a) Determine the expectation value of \( x \). (b) Determine the probability of finding the particle near \( \frac{L}{4} \) by calculating the probability that the particle lies in the range \( 0.490L \leq x \leq 0.510L \). (c) What If? Determine the probability of finding the particle near \( \frac{L}{4} \) by calculating the probability that the particle lies in the range \( 0.240L \leq x \leq 0.260L \).
(d) Argue that the result of part (a) does not contradict the results of parts (b) and (c).

20. An electron in an infinitely deep square well has a wave function that is given by

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin \left( \frac{\pi n x}{L} \right)$$

for $0 \leq x \leq L$ and is zero otherwise. (a) What are the most probable positions of the electron? (b) Explain how you identify them.

21. An electron is trapped in an infinitely deep potential well 0.300 nm in length. (a) If the electron is in its ground state, what is the probability of finding it within 0.100 nm of the left-hand wall? (b) Identify the classical probability of finding the electron in this interval and state how it compares with the answer to part (a). (c) Repeat parts (a) and (b) assuming the particle is in the 99th energy state.

22. A quantum particle is in the $n = 1$ state of an infinitely deep square well with walls at $x = 0$ and $x = L$. Let $\ell$ be an arbitrary value of $x$ between $x = 0$ and $x = L$. (a) Find an expression for the probability, as a function of $\ell$, that the particle will be found between $x = 0$ and $x = \ell$. (b) Sketch the probability as a function of the variable $\ell/L$. Choose values of $\ell/L$ ranging from 0 to 1.00 in steps of 0.100. (c) Explain why the probability function must have particular values at $\ell/L = 0$ and at $\ell/L = 1$. (d) Find the value of $\ell$ for which the probability of finding the particle between $x = 0$ and $x = \ell$ is twice the probability of finding the particle between $x = \ell$ and $x = L$. Suggestion: Solve the transcendental equation for $\ell/L$ numerically.

23. A quantum particle in an infinitely deep square well has a wave function that is given by

$$\psi_1(x) = \sqrt{\frac{2}{L}} \sin \left( \frac{\pi x}{L} \right)$$

for $0 \leq x \leq L$ and is zero otherwise. (a) Determine the probability of finding the particle between $x = 0$ and $x = L/2$. (b) Use the result of this calculation and a symmetry argument to find the probability of finding the particle between $x = L/2$ and $x = L$. Do not re-evaluate the integral.

Section 41.3 The Schrödinger Equation

24. Show that the wave function $\psi = Ae^{ikx-\omega t}$ is a solution to the Schrödinger equation (Eq. 41.15), where $k = 2\pi/\lambda$ and $U = 0$.

25. The wave function of a quantum particle of mass $m$ is

$$\psi(x) = A \cos (kx) + B \sin (kx)$$

where $A$, $B$, and $k$ are constants. (a) Assuming the particle is free ($U = 0$), show that $\psi(x)$ is a solution of the Schrödinger equation (Eq. 41.15). (b) Find the corresponding energy $E$ of the particle.

26. Consider a quantum particle moving in a one-dimensional box for which the walls are at $x = -L/2$ and $x = L/2$. (a) Write the wave functions and probability densities for $n = 1$, $n = 2$, and $n = 3$. (b) Sketch the wave functions and probability densities.

27. In a region of space, a quantum particle with zero total energy has a wave function

$$\psi(x) = Axe^{-\sqrt{\frac{\hbar}{mE}}x^2}$$

(a) Find the potential energy $U$ as a function of $x$. (b) Make a sketch of $U(x)$ versus $x$.

28. A quantum particle of mass $m$ moves in a potential well of length $2L$. Its potential energy is infinite for $x < -L$ and for $x > +L$. In the region $-L < x < L$, its potential energy is given by

$$U(x) = \frac{-\hbar^2 x^2}{2mL^2}$$

In addition, the particle is in a stationary state that is described by the wave function $\psi(x) = A(1 - x^2/L^2)$ for $-L < x < +L$ and by $\psi(x) = 0$ elsewhere. (a) Determine the energy of the particle in terms of $n$, $m$, and $L$. (b) Determine the normalization constant $A$. (c) Determine the probability that the particle is located between $x = -L/3$ and $x = +L/3$.

Section 41.4 A Particle in a Well of Finite Height

29. Sketch (a) the wave function $\psi(x)$ and (b) the probability density $|\psi(x)|^2$ for the $n = 4$ state of a quantum particle in a finite potential well. (See Fig. 41.7.)

30. Suppose a quantum particle is in its ground state in a box that has infinitely high walls (see Fig. 41.4a). Now suppose the left-hand wall is suddenly lowered to a finite height and width. (a) Qualitatively sketch the wave function for the particle a short time later. (b) If the box has a length $L$, what is the wavelength of the wave that penetrates the left-hand wall?

Section 41.5 Tunneling Through a Potential Energy Barrier

31. An electron with kinetic energy $E = 5.00$ eV is incident on a barrier of width $L = 0.200$ nm and height $U = 10.0$ eV (Fig. P41.31). What is the probability that the electron (a) tunnels through the barrier? (b) Is reflected?

32. An electron having total energy $E = 4.50$ eV approaches a rectangular energy barrier with $U = 5.00$ eV and $L = 950$ pm as shown in Figure P41.31. Classically, the electron cannot pass through the barrier because $E < U$. Quantum-mechanically, however, the probability of tunneling is not zero. (a) Calculate this probability, which is the transmission coefficient. (b) To what value would the width $L$ of the potential barrier have to be increased for the chance of an inci-
dent 4.50-eV electron tunneling through the barrier to be one in one million?

33. An electron has a kinetic energy of 12.0 eV. The electron is incident upon a rectangular barrier of height 20.0 eV and width 1.00 nm. If the electron absorbed all the energy of a photon of green light (with wavelength 546 nm) at the instant it reached the barrier, by what factor would the electron’s probability of tunneling through the barrier increase?

Section 41.6 Applications of Tunneling

34. A scanning tunneling microscope (STM) can precisely determine the depths of surface features because the current through its tip is very sensitive to differences in the width of the gap between the tip and the sample surface. Assume the electron wave function falls off exponentially in this direction with a decay length of 0.100 nm, that is, with \( C = 10.0 \text{ nm}^{-1} \). Determine the ratio of the current when the STM tip is 0.500 nm above a surface feature to the current when the tip is 0.515 nm above the surface.

35. The design criterion for a typical scanning tunneling microscope (STM) specifies that it must be able to detect, on the sample below its tip, surface features that differ in height by only 0.002 00 nm. Assuming the electron transmission coefficient is \( e^{-2Ct} \) with \( C = 10.0 \text{ nm}^{-1} \), what percentage change in electron transmission must the electronics of the STM be able to detect to achieve this resolution?

Section 41.7 The Simple Harmonic Oscillator

36. A one-dimensional harmonic oscillator wave function is 
\[ \psi = A e^{-kx} \]
(a) Show that \( \psi \) satisfies Equation 41.24. (b) Find \( b \) and the total energy \( E \). (c) Is this wave function for the ground state or for the first excited state?

37. A quantum simple harmonic oscillator consists of an electron bound by a restoring force proportional to its position relative to a certain equilibrium point. The proportionality constant is 8.99 N/m. What is the longest wavelength of light that can excite the oscillator?

38. A quantum simple harmonic oscillator consists of a particle of mass \( m \) bound by a restoring force proportional to its position relative to a certain equilibrium point. The proportionality constant is \( k \). What is the longest wavelength of light that can excite the oscillator?

39. (a) Normalize the wave function for the ground state of a simple harmonic oscillator. That is, apply Equation 41.7 to Equation 41.26 and find the required value for the constant \( B \) in terms of \( m \), \( \omega \), and fundamental constants. (b) Determine the proportionality of finding the oscillator in a narrow interval \(-\delta/2 < x < \delta/2\) around its equilibrium position.

40. Two particles with masses \( m_1 \) and \( m_2 \) are joined by a light spring of force constant \( k \). They vibrate along a straight line with their center of mass fixed. (a) Show that the total energy can be written as 
\[ \frac{1}{2} m_1 u_1^2 + \frac{1}{2} m_2 u_2^2 + \frac{1}{2} k x^2 \]
(b) Differentiate the equation with respect to \( x \). Proceed to show that the system executes simple harmonic motion. (c) Find its frequency.

41. The total energy of a particle–spring system in which the particle moves with simple harmonic motion along the \( x \) axis is
\[ E = \frac{p_x^2}{2m} + \frac{k x^2}{2} \]
where \( p_x \) is the momentum of the quantum particle and \( k \) is the spring constant. (a) Using the uncertainty principle, show that this expression can also be written as
\[ E \approx \frac{p_x^2}{2m} + \frac{k h^2}{8p_x^2} \]
(b) Show that the minimum energy of the harmonic oscillator is
\[ E_{\text{min}} = K + U = \frac{1}{2} h \sqrt{\frac{k}{m} + \frac{h \omega}{4}} = \frac{h \omega}{2} \]

42. Show that Equation 41.26 is a solution of Equation 41.24 with energy \( E = \frac{1}{2} h \omega \).

Additional Problems

43. A particle of mass \( 2.00 \times 10^{-28} \text{ kg} \) is confined to a one-dimensional box of length \( 1.00 \times 10^{-10} \text{ m} \). For \( n = 1 \), what are (a) the particle’s wavelength, (b) its momentum, and (c) its ground-state energy?

44. Prove that the first term in the Schrödinger equation, \(-(\hbar^2/2m)(d^2/\text{dx}^2)\), reduces to the kinetic energy of the quantum particle multiplied by the wave function (a) for a freely moving particle, with the wave function given by Equation 41.4, and (b) for a particle in a box, with the wave function given by Equation 41.13.

45. A particle in a one-dimensional box of length \( L \) is in its first excited state, corresponding to \( n = 2 \). Determine the probability of finding the particle between \( x = 0 \) and \( x = L/4 \).

46. Prove that assuming \( n = 0 \) for a quantum particle in an infinitely deep potential well leads to a violation of the uncertainty principle \( \Delta p_x \Delta x \approx \hbar/2 \).

47. Calculate the transmission probability for quantum-mechanical tunneling in each of the following cases. (a) An electron with an energy deficit of \( U = E = 0.010 \text{ eV} \) is incident on a square barrier of width \( L = 0.18 \text{ nm} \). (b) An electron with an energy deficit of \( 1.00 \text{ eV} \) is incident on the same barrier. (c) An alpha particle (mass \( 6.64 \times 10^{-27} \text{ kg} \)) with an energy deficit
of 1.00 MeV is incident on a square barrier of width 1.00 fm. (d) An 8.00-kg bowling ball with an energy deficit of 1.00 J is incident on a square barrier of width 2.00 cm.

48. An electron in an infinitely deep potential well has a ground-state energy of 0.300 eV. (a) Show that the photon emitted in a transition from the $n = 3$ state to the $n = 1$ state has a wavelength of 517 nm, which makes it green visible light. (b) Find the wavelength and the spectral region for each of the other five transitions that take place among the four lowest energy levels.

49. An atom in an excited state 1.80 eV above the ground state remains in that excited state 2.00 µs before moving to the ground state. Find (a) the frequency and (b) the wavelength of the emitted photon. (c) Find the approximate uncertainty in energy of the photon.

50. A marble rolls back and forth across a shoebox at a constant speed of 0.8 m/s. Make an order-of-magnitude estimate of the probability of it escaping through the wall of the box by quantum tunneling. State the quantities you take as data and the values you measure or estimate for them.

51. An electron confined to a box absorbs a photon with wavelength $\lambda$. As a result, the electron makes a transition from the $n = 1$ state to the $n = 3$ state. (a) Find the length of the box. (b) What is the wavelength $\lambda'$ of the photon emitted when the electron makes a transition from the $n = 3$ state to the $n = 2$ state?

52. For a quantum particle described by a wave function $\psi(x)$, the expectation value of a physical quantity $f(x)$ associated with the particle is defined by

$$\langle f(x) \rangle = \int_{-\infty}^{\infty} \psi^* f(x) \psi \, dx$$

For a particle in an infinitely deep one-dimensional box extending from $x = 0$ to $x = L$, show that

$$\langle x^2 \rangle = \frac{L^2}{3} - \frac{L^2}{2n^2\pi^2}$$

53. A quantum particle of mass $m$ is placed in a one-dimensional box of length $L$. Assume the box is so small that the particle’s motion is relativistic and $K = p^2/2m$ is not valid. (a) Derive an expression for the kinetic energy levels of the particle. (b) Assume the particle is an electron in a box of length $L = 1.00 \times 10^{-13}$ m. Find its lowest possible kinetic energy. (c) By what percent is the nonrelativistic expression in error? Suggestion: See Equation 39.23.

54. Why is the following situation impossible? A particle is in the ground state of an infinite square well of length $L$. A light source is adjusted so that the photons of wavelength $\lambda$ are absorbed by the particle as it makes a transition to the first excited state. An identical particle is in the ground state of a finite square well of length $L$. The light source sends photons of the same wavelength $\lambda$ toward this particle. The photons are not absorbed because the allowed energies of the finite square well are different from those of the infinite square well. To cause the photons to be absorbed, you move the light source at a high speed toward the particle in the finite square well. You are able to find a speed at which the Doppler-shifted photons are absorbed as the particle makes a transition to the first excited state.

55. A quantum particle has a wave function

$$\psi(x) = \begin{cases} \sqrt{\frac{2}{a}} e^{-x^2/a} & \text{for } x > 0 \\ 0 & \text{for } x < 0 \end{cases}$$

(a) Find and sketch the probability density. (b) Find the probability that the particle will be at any point where $x < 0$. (c) Show that $\psi$ is normalized and then (d) find the probability of finding the particle between $x = 0$ and $x = a$.

56. An electron is confined to move in the $xy$ plane in a rectangle whose dimensions are $L_x$ and $L_y$. That is, the electron is trapped in a two-dimensional potential well having lengths of $L_x$ and $L_y$. In this situation, the allowed energies of the electron depend on two quantum numbers $n_x$ and $n_y$ and are given by

$$E = \frac{\hbar^2}{8m_e} \left( \frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} \right)$$

Using this information, we wish to find the wavelength of a photon needed to excite the electron from the ground state to the second excited state, assuming $L_x = L_y = L$. (a) Assuming the wave function on the lengths, write an expression for the allowed energies of the electron in terms of the quantum numbers $n_x$ and $n_y$. (b) What values of $n_x$ and $n_y$ correspond to the ground state? (c) Find the energy of the ground state. (d) What are the possible values of $n_x$ and $n_y$ for the first excited state, that is, the next-highest state in terms of energy? (e) What are the possible values of $n_x$ and $n_y$ for the second excited state? (f) Using the values in part (c), what is the energy of the second excited state? (g) What is the energy difference between the ground state and the second excited state? (h) What is the wavelength of a photon that will cause the transition between the ground state and the second excited state?

57. The normalized wave functions for the ground state, $\psi_0(x)$, and the first excited state, $\psi_1(x)$, of a quantum harmonic oscillator are

$$\psi_0(x) = \left( \frac{a}{\pi} \right)^{1/4} e^{-ax^2/2} \quad \psi_1(x) = \left( \frac{4a^3}{\pi} \right)^{1/4} xe^{-ax^2/2}$$

where $a = ma^2/\hbar$. A mixed state, $\psi_0(x)$, is constructed from these states:

$$\psi_0(x) = \frac{1}{\sqrt{2}} [\psi_0(x) + \psi_1(x)]$$

The symbol $\langle \psi \rangle$, denotes the expectation value of the quantity $\psi$ for the state $\psi(x)$. Calculate the expectation values (a) $\langle x \rangle_0$, (b) $\langle x \rangle_1$, and (c) $\langle x \rangle_0$.

58. A two-slit electron diffraction experiment is done with slits of unequal widths. When only slit 1 is open, the
number of electrons reaching the screen per second is 25.0 times the number of electrons reaching the screen per second when only slit 2 is open. When both slits are open, an interference pattern results in which the destructive interference is not complete. Find the ratio of the probability of an electron arriving at an interference maximum to the probability of an electron arriving at an adjacent interference minimum. Suggestion: Use the superposition principle.

Challenge Problems

59. Particles incident from the left in Figure P41.59 are confronted with a step in potential energy. The step has a height $U$ at $x = 0$. The particles have energy $E > U$. Classically, all the particles would continue moving forward with reduced speed. According to quantum mechanics, however, a fraction of the particles are reflected at the step. (a) Prove that the reflection coefficient $R$ for this case is

$$ R = \frac{(k_1 - k_2)^2}{(k_1 + k_2)^2} $$

where $k_1 = \frac{2\pi}{\lambda_1}$ and $k_2 = \frac{2\pi}{\lambda_2}$ are the wave numbers for the incident and transmitted particles, respectively. Proceed as follows. Show that the wave function $\psi_1 = A e^{ik_1 x} + B e^{-ik_2 x}$ satisfies the Schrödinger equation in region 1, for $x < 0$. Here $A e^{ik_1 x}$ represents the incident beam and $B e^{-ik_2 x}$ represents the reflected particles. Show that $\psi_2 = C e^{ik_2 x}$ satisfies the Schrödinger equation in region 2, for $x > 0$. Impose the boundary conditions $\psi_1 = \psi_2$ and $d\psi_1/dx = d\psi_2/dx$, at $x = 0$, to find the relationship between $B$ and $A$. Then evaluate $R = B^2/A^2$. A particle that has kinetic energy $E = 7.00 \text{ eV}$ is incident from a region where the potential energy is zero onto one where $U = 5.00 \text{ eV}$. Find (b) its probability of being reflected and (c) its probability of being transmitted.

![Figure P41.59](image)

60. Consider a “crystal” consisting of two fixed ions of charge +$e$ and two electrons as shown in Figure P41.60. (a) Taking into account all the pairs of interactions, find the potential energy of the system as a function of $d$. (b) Assuming the electrons to be restricted to a one-dimensional box of length $3d$, find the minimum kinetic energy of the two electrons. (c) Find the value of $d$ for which the total energy is a minimum. (d) State how this value of $d$ compares with the spacing of atoms in lithium, which has a density of 0.530 g/cm$^3$ and a molar mass of 6.94 g/mol.

61. An electron is trapped in a quantum dot. The quantum dot may be modeled as a one-dimensional, rigid-walled box of length 1.00 nm. (a) Taking $x = 0$ as the left side of the box, calculate the probability of finding the electron between $x_1 = 0.150$ nm and $x_2 = 0.350$ nm for the $n = 1$ state. (b) Repeat part (a) for the $n = 2$ state. Calculate the energies in electron volts of (c) the $n = 1$ state and (d) the $n = 2$ state.

62. An electron is represented by the time-independent wave function

$$ \psi(x) = \begin{cases} A e^{-ax} & \text{for } x > 0 \\ A e^{+ax} & \text{for } x < 0 \end{cases} $$

(a) Sketch the wave function as a function of $x$. (b) Sketch the probability density representing the likelihood that the electron is found between $x$ and $x + dx$. (c) Only an infinite value of potential energy could produce the discontinuity in the derivative of the wave function at $x = 0$. Aside from this feature, argue that $\psi(x)$ can be a physically reasonable wave function. (d) Normalize the wave function. (e) Determine the probability of finding the electron somewhere in the range $-\frac{1}{2a} \leq x \leq \frac{1}{2a}$.

63. The wave function

$$ \psi(x) = B e^{-(\omega x/2\hbar)^2} $$

is a solution to the simple harmonic oscillator problem. (a) Find the energy of this state. (b) At what position are you least likely to find the particle? (c) At what positions are you most likely to find the particle? (d) Determine the value of $B$ required to normalize the wave function. (e) What if? Determine the classical probability of finding the particle in an interval of small length $\delta$ centered at the position $x = 2(\hbar/\omega)^{1/2}$. (f) What is the actual probability of finding the particle in this interval?

64. (a) Find the normalization constant $A$ for a wave function made up of the two lowest states of a quantum particle in a box extending from $x = 0$ to $x = L$:

$$ \psi(x) = A \left[ \sin \left( \frac{\pi x}{L} \right) + 4 \sin \left( \frac{2\pi x}{L} \right) \right] $$

(b) A particle is described in the space $-a \leq x \leq a$ by the wave function

$$ \psi(x) = A \cos \left( \frac{\pi x}{2a} \right) + B \sin \left( \frac{\pi x}{a} \right) $$

Determine the relationship between the values of $A$ and $B$ required for normalization.
In Chapter 41, we introduced some basic concepts and techniques used in quantum mechanics along with their applications to various one-dimensional systems. In this chapter, we apply quantum mechanics to atomic systems. A large portion of the chapter is focused on the application of quantum mechanics to the study of the hydrogen atom. Understanding the hydrogen atom, the simplest atomic system, is important for several reasons:

- The hydrogen atom is the only atomic system that can be solved exactly.
- Much of what was learned in the 20th century about the hydrogen atom, with its single electron, can be extended to such single-electron ions as He$^+$ and Li$^{2+}$.
- The hydrogen atom is an ideal system for performing precise tests of theory against experiment and for improving our overall understanding of atomic structure.
The quantum numbers that are used to characterize the allowed states of hydrogen can also be used to investigate more complex atoms, and such a description enables us to understand the periodic table of the elements. This understanding is one of the greatest triumphs of quantum mechanics.

The basic ideas about atomic structure must be well understood before we attempt to deal with the complexities of molecular structures and the electronic structure of solids.

The full mathematical solution of the Schrödinger equation applied to the hydrogen atom gives a complete and beautiful description of the atom’s properties. Because the mathematical procedures involved are beyond the scope of this text, however, many details are omitted. The solutions for some states of hydrogen are discussed, together with the quantum numbers used to characterize various allowed states. We also discuss the physical significance of the quantum numbers and the effect of a magnetic field on certain quantum states.

A new physical idea, the exclusion principle, is presented in this chapter. This principle is extremely important for understanding the properties of multielectron atoms and the arrangement of elements in the periodic table.

Finally, we apply our knowledge of atomic structure to describe the mechanisms involved in the production of x-rays and in the operation of a laser.

### 42.1 Atomic Spectra of Gases

As pointed out in Section 40.1, all objects emit thermal radiation characterized by a continuous distribution of wavelengths. In sharp contrast to this continuous-distribution spectrum is the discrete line spectrum observed when a low-pressure gas undergoes an electric discharge. (Electric discharge occurs when the gas is subject to a potential difference that creates an electric field greater than the dielectric strength of the gas.) Observation and analysis of these spectral lines is called emission spectroscopy.

When the light from a gas discharge is examined using a spectrometer (see Fig. 38.15), it is found to consist of a few bright lines of color on a generally dark background. This discrete line spectrum contrasts sharply with the continuous rainbow of colors seen when a glowing solid is viewed through the same instrument. Figure 42.1a (page 1298) shows that the wavelengths contained in a given line spectrum are characteristic of the element emitting the light. The simplest line spectrum is that for atomic hydrogen, and we describe this spectrum in detail. Because no two elements have the same line spectrum, this phenomenon represents a practical and sensitive technique for identifying the elements present in unknown samples.

Another form of spectroscopy very useful in analyzing substances is absorption spectroscopy. An absorption spectrum is obtained by passing white light from a continuous source through a gas or a dilute solution of the element being analyzed. The absorption spectrum consists of a series of dark lines superimposed on the continuous spectrum of the light source as shown in Figure 42.1b for atomic hydrogen.

The absorption spectrum of an element has many practical applications. For example, the continuous spectrum of radiation emitted by the Sun must pass through the cooler gases of the solar atmosphere. The various absorption lines observed in the solar spectrum have been used to identify elements in the solar atmosphere. In early studies of the solar spectrum, experimenters found some lines that did not correspond to any known element. A new element had been discovered!
The new element was named helium, after the Greek word for Sun, helios. Helium was subsequently isolated from subterranean gas on the Earth. Using this technique, scientists have examined the light from stars other than our Sun and have never detected elements other than those present on the Earth. Absorption spectroscopy has also been useful in analyzing heavy-metal contamination of the food chain. For example, the first determination of high levels of mercury in tuna was made with the use of atomic absorption spectroscopy.

The discrete emissions of light from gas discharges are used in “neon” signs such as those in the opening photograph of this chapter. Neon, the first gas used in these types of signs and the gas after which these signs are named, emits strongly in the red region. As a result, a glass tube filled with neon gas emits bright red light when an applied voltage causes a continuous discharge. Early signs used different gases to provide different colors, although the brightness of these signs was generally very low. Many present-day “neon” signs contain mercury vapor, which emits strongly in the ultraviolet range of the electromagnetic spectrum. The inside of a present-day sign’s glass tube is coated with a material that emits a particular color when it absorbs ultraviolet radiation from the mercury. The color of the light from the tube results from the particular material chosen. A household fluorescent light operates in the same manner, with a white-emitting material coating the inside of the glass tube.

From 1860 to 1885, scientists accumulated a great deal of data on atomic emissions using spectroscopic measurements. In 1885, a Swiss schoolteacher, Johann Jacob Balmer (1825–1898), found an empirical equation that correctly predicted the wavelengths of four visible emission lines of hydrogen: H\(_a\) (red), H\(_b\) (blue-green), H\(_g\) (blue-violet), and H\(_d\) (violet). Figure 42.2 shows these and other lines (in the ultraviolet) in the emission spectrum of hydrogen. The complete set of lines is called the Balmer series. The wavelengths of these lines can be described by the following equation, which is a modification made by Johannes Rydberg (1854–1919) of Balmer’s original equation:

\[
\frac{1}{\lambda} = R_H \left( \frac{1}{2^2} - \frac{1}{n^2} \right) \quad n = 3, 4, 5, \ldots
\]

where \( R_H \) is a constant now called the Rydberg constant with a value of \( 1.097 373 \times 10^{-7} \text{ m}^{-1} \). The integer values of \( n \) from 3 to 6 give the four visible lines from 656.3 nm (red) down to 410.2 nm (violet). Equation 42.1 also describes the ultraviolet spectral lines in the Balmer series if \( n \) is carried out beyond \( n = 6 \). The series limit is the shortest wavelength in the series and corresponds to \( n \rightarrow \infty \), with a wavelength of 364.6 nm as in Figure 42.2. The measured spectral lines agree with the empirical equation, Equation 42.1, to within 0.1%.
Other lines in the spectrum of hydrogen were found following Balmer’s discovery. These spectra are called the Lyman, Paschen, and Brackett series after their discoverers. The wavelengths of the lines in these series can be calculated through the use of the following empirical equations:

$$\frac{1}{\lambda} = R_H \left(1 - \frac{1}{n^2}\right) \quad n = 2, 3, 4, \ldots \quad (42.2)$$  

Lyman series

$$\frac{1}{\lambda} = R_H \left(1 - \frac{1}{n^2}\right) \quad n = 4, 5, 6, \ldots \quad (42.3)$$  

Paschen series

$$\frac{1}{\lambda} = R_H \left(1 - \frac{1}{n^2}\right) \quad n = 5, 6, 7, \ldots \quad (42.4)$$  

Brackett series

No theoretical basis existed for these equations; they simply worked. The same constant $R_H$ appears in each equation, and all equations involve small integers. In Section 42.3, we shall discuss the remarkable achievement of a theory for the hydrogen atom that provided an explanation for these equations.

### 42.2 Early Models of the Atom

The model of the atom in the days of Newton was a tiny, hard, indestructible sphere. Although this model provided a good basis for the kinetic theory of gases (Chapter 21), new models had to be devised when experiments revealed the electrical nature of atoms. In 1897, J. J. Thomson established the charge-to-mass ratio for electrons. (See Fig. 29.15 in Section 29.3.) The following year, he suggested a model that describes the atom as a region in which positive charge is spread out in space with electrons embedded throughout the region, much like the seeds in a watermelon or raisins in thick pudding (Fig. 42.3). The atom as a whole would then be electrically neutral.

In 1911, Ernest Rutherford (1871–1937) and his students Hans Geiger and Ernest Marsden performed a critical experiment that showed that Thomson’s model could not be correct. In this experiment, a beam of positively charged alpha particles (helium nuclei) was projected into a thin metallic foil such as the target in Figure 42.4a (page 1300). Most of the particles passed through the foil as if it were empty space, but some of the results of the experiment were astounding. Many of the particles deflected from their original direction of travel were scattered through large angles. Some particles were even deflected backward, completely reversing their direction of travel! When Geiger informed Rutherford that some alpha particles were scattered backward, Rutherford wrote, “It was quite the most incredible event that has ever happened to me in my life. It was almost as incredible as if you fired a 15-inch [artillery] shell at a piece of tissue paper and it came back and hit you.”

Such large deflections were not expected on the basis of Thomson’s model. According to that model, the positive charge of an atom in the foil is spread out over such a great volume (the entire atom) that there is no concentration of positive charge strong enough to cause any large-angle deflections of the positively charged alpha particles. Furthermore, the electrons are so much less massive than the alpha particles that they would not cause large-angle scattering either. Rutherford explained his astonishing results by developing a new atomic model, one that assumed the positive charge in the atom was concentrated in a region that was small relative to the size of the atom. He called this concentration of positive charge the nucleus of the atom. Any electrons belonging to the atom were assumed to be in the relatively large volume outside the nucleus. To explain why these electrons were not pulled into the nucleus by the attractive electric force, Rutherford modeled them as moving in orbits around the nucleus in the same manner as the planets orbit the Sun (Fig. 42.4b). For this reason, this model is often referred to as the planetary model of the atom.

Two basic difficulties exist with Rutherford’s planetary model. As we saw in Section 42.1, an atom emits (and absorbs) certain characteristic frequencies of...
electromagnetic radiation and no others, but the Rutherford model cannot explain this phenomenon. A second difficulty is that Rutherford’s electrons are described by the particle in uniform circular motion model; they have a centripetal acceleration. According to Maxwell’s theory of electromagnetism, centripetally accelerated charges revolving with frequency $f$ should radiate electromagnetic waves of frequency $f$. Unfortunately, this classical model leads to a prediction of self-destruction when applied to the atom. Identifying the electron and the proton as a nonisolated system for energy, Equation 8.2 becomes $\Delta K + \Delta U = T_{\text{ER}}$, where $K$ is the kinetic energy of the electron, $U$ is the electric potential energy of the electron–nucleus system, and $T_{\text{ER}}$ represents the outgoing electromagnetic radiation. As energy leaves the system, the radius of the electron’s orbit steadily decreases (Fig. 42.5). The system is an isolated system for angular momentum because there is no torque on the system. Therefore, as the electron moves closer to the nucleus, the angular speed of the electron will increase, just like the spinning skater in Figure 11.10 in Section 11.4. This process leads to an ever-increasing frequency of emitted radiation and an ultimate collapse of the atom as the electron plunges into the nucleus.

### 42.3 Bohr’s Model of the Hydrogen Atom

Given the situation described at the end of Section 42.2, the stage was set for Niels Bohr in 1913 when he presented a new model of the hydrogen atom that circumvented the difficulties of Rutherford’s planetary model. Bohr applied Planck’s ideas of quantized energy levels (Section 40.1) to Rutherford’s orbiting atomic electrons. Bohr’s theory was historically important to the development of quantum physics, and it appeared to explain the spectral line series described by Equations 42.1 through 42.4. Although Bohr’s model is now considered obsolete and has been completely replaced by a probabilistic quantum-mechanical theory, we can use the Bohr model to develop the notions of energy quantization and angular momentum quantization as applied to atomic-sized systems.

Bohr combined ideas from Planck’s original quantum theory, Einstein’s concept of the photon, Rutherford’s planetary model of the atom, and Newtonian mechanics to arrive at a semiclassical structural model based on some revolutionary ideas. The structural model of the Bohr theory as it applies to the hydrogen atom has the following properties:

1. **Physical components:**
   - The electron moves in circular orbits around the proton under the influence of the electric force of attraction as shown in Figure 42.6.
2. Behavior of the Components:

(a) Only certain electron orbits are stable. When in one of these stationary states, as Bohr called them, the electron does not emit energy in the form of radiation, even though it is accelerating. Hence, the total energy of the atom remains constant and classical mechanics can be used to describe the electron’s motion. Bohr’s model claims that the centripetally accelerated electron does not continuously emit radiation, losing energy and eventually spiraling into the nucleus, as predicted by classical physics in the form of Rutherford’s planetary model.

(b) The atom emits radiation when the electron makes a transition from a more energetic initial stationary state to a lower-energy stationary state. This transition cannot be visualized or treated classically. In particular, the frequency \( f \) of the photon emitted in the transition is related to the change in the atom’s energy and is not equal to the frequency of the electron’s orbital motion. The frequency of the emitted radiation is found from the energy-conservation expression

\[
E_i - E_f = hf
\]  

(42.5)

where \( E_i \) is the energy of the initial state, \( E_f \) is the energy of the final state, and \( E_i > E_f \). In addition, energy of an incident photon can be absorbed by the atom, but only if the photon has an energy that exactly matches the difference in energy between an allowed state of the atom and a higher-energy state. Upon absorption, the photon disappears and the atom makes a transition to the higher-energy state.

(c) The size of an allowed electron orbit is determined by a condition imposed on the electron’s orbital angular momentum: the allowed orbits are those for which the electron’s orbital angular momentum about the nucleus is quantized and equal to an integral multiple of \( \hbar = \hbar / 2\pi \),

\[
m_e v r = n \hbar \quad n = 1, 2, 3, \ldots
\]  

(42.6)

where \( m_e \) is the electron mass, \( v \) is the electron’s speed in its orbit, and \( r \) is the orbital radius.

These postulates are a mixture of established principles and completely new and untested ideas at the time. Property 1, from classical mechanics, treats the electron in orbit around the nucleus in the same way we treat a planet in a circular orbit around a star, using the particle in uniform circular motion analysis model. Property 2(a) was a radical new idea in 1913 that was completely at odds with the understanding of electromagnetism at the time. Property 2(b) represents the principle of conservation of energy as described by the nonisolated system model for energy. Property 2(c) is another new idea that had no basis in classical physics.

Property 2(b) implies qualitatively the existence of a characteristic discrete emission line spectrum and also a corresponding absorption line spectrum of the kind shown in Figure 42.1 for hydrogen. Using these postulates, let’s calculate the allowed energy levels and find quantitative values of the emission wavelengths of the hydrogen atom.

The electric potential energy of the system shown in Figure 42.6 is given by Equation 25.13, \( U = k_e q_1 q_2 / r = -k_e e^2 / r \), where \( k_e \) is the Coulomb constant and the negative sign arises from the charge \(-e\) on the electron. Therefore, the total energy of the atom, which consists of the electron’s kinetic energy and the system’s potential energy, is

\[
E = K + U = \frac{1}{2} m_e v^2 - k_e \frac{e^2}{r}
\]  

(42.7)
The electron is modeled as a particle in uniform circular motion, so the electric force $k_e e^2/r^2$ exerted on the electron must equal the product of its mass and its centripetal acceleration ($a_c = v^2/r$):

$$\frac{k_e e^2}{r^2} = \frac{m_e v^2}{r}$$

$$v^2 = \frac{k_e e^2}{m_e r} \tag{42.8}$$

From Equation 42.8, we find that the kinetic energy of the electron is

$$K = \frac{1}{2} m_e v^2 = \frac{k_e e^2}{2r}$$

Substituting this value of $K$ into Equation 42.7 gives the following expression for the total energy of the atom:

$$E = -\frac{k_e e^2}{2r} \tag{42.9}$$

Because the total energy is negative, which indicates a bound electron–proton system, energy in the amount of $k_e e^2/2r$ must be added to the atom to remove the electron and make the total energy of the system zero.

We can obtain an expression for $r$, the radius of the allowed orbits, by solving Equation 42.6 for $v^2$ and equating it to Equation 42.8:

$$v^2 = \frac{n^2 \hbar^2}{m_e r^2} = \frac{k_e e^2}{m_e r}$$

$$r_n = \frac{n^2 \hbar^2}{m_e k_e e^2} \quad n = 1, 2, 3, \ldots \tag{42.10}$$

Equation 42.10 shows that the radii of the allowed orbits have discrete values; they are quantized. The result is based on the assumption that the electron can exist only in certain allowed orbits determined by the integer $n$ (Bohr’s Property 2(c)).

The orbit with the smallest radius, called the Bohr radius $a_0$, corresponds to $n = 1$ and has the value

$$a_0 = \frac{\hbar^2}{m_e k_e e^2} = 0.0529 \text{ nm} \tag{42.11}$$

Substituting Equation 42.11 into Equation 42.10 gives a general expression for the radius of any orbit in the hydrogen atom:

$$r_n = n^2 a_0 = n^2(0.0529 \text{ nm}) \quad n = 1, 2, 3, \ldots \tag{42.12}$$

Bohr’s theory predicts a value for the radius of a hydrogen atom on the right order of magnitude, based on experimental measurements. This result was a striking triumph for Bohr’s theory. The first three Bohr orbits are shown to scale in Figure 42.7.

The quantization of orbit radii leads to energy quantization. Substituting $r_n = n^2 a_0$ into Equation 42.9 gives

$$E_n = -\frac{k_e e^2}{2n a_0} \left(\frac{1}{n^2}\right) \quad n = 1, 2, 3, \ldots \tag{42.13}$$

Inserting numerical values into this expression, we find that

$$E_n = -\frac{13.606 \text{ eV}}{n^2} \quad n = 1, 2, 3, \ldots \tag{42.14}$$

*Compare Equation 42.9 with its gravitational counterpart, Equation 13.19.*
Only energies satisfying this equation are permitted. The lowest allowed energy level, the ground state, has \( n = 1 \) and energy \( E_1 = -13.606 \) eV. The next energy level, the first excited state, has \( n = 2 \) and energy \( E_2 = E_1/2^2 = -3.401 \) eV. Figure 42.8 is an energy-level diagram showing the energies of these discrete energy states and the corresponding quantum numbers \( n \). The uppermost level corresponds to \( n = \infty \) (or \( r = \infty \)) and \( E = 0 \).

Notice how the allowed energies of the hydrogen atom differ from those of the particle in a box. The particle-in-a-box energies (Eq. 41.14) increase as \( n^2 \), so they become farther apart in energy as \( n \) increases. On the other hand, the energies of the hydrogen atom (Eq. 42.14) are inversely proportional to \( n^2 \), so their separation in energy becomes smaller as \( n \) increases. The separation between energy levels approaches zero as \( n \) approaches infinity and the energy approaches zero.

Zero energy represents the boundary between a bound system of an electron and a proton and an unbound system. If the energy of the atom is raised from that of the ground state to any energy larger than zero, the atom is ionized. The minimum energy required to ionize the atom in its ground state is called the ionization energy. As can be seen from Figure 42.8, the ionization energy for hydrogen in the ground state, based on Bohr’s calculation, is 13.6 eV. This finding constituted another major achievement for the Bohr theory because the ionization energy for hydrogen had already been measured to be 13.6 eV.

Equations 42.5 and 42.13 can be used to calculate the frequency of the photon emitted when the electron makes a transition from an outer orbit to an inner orbit:

\[
\frac{1}{\lambda} = \frac{f}{c} = \frac{k_e e^2}{2a_0 \hbar c} \left( \frac{1}{n_i^2} - \frac{1}{n_f^2} \right)
\]

Because the quantity measured experimentally is wavelength, it is convenient to use \( c = \lambda f \) to express Equation 42.15 in terms of wavelength:

\[
\frac{1}{\lambda} = \frac{f}{c} = \frac{k_e e^2}{2a_0 \hbar c} \left( \frac{1}{n_i^2} - \frac{1}{n_f^2} \right)
\]

Remarkably, this expression, which is purely theoretical, is identical to the general form of the empirical relationships discovered by Balmer and Rydberg and given by Equations 42.1 to 42.4:

\[
\frac{1}{\lambda} = R_H \left( \frac{1}{n_i^2} - \frac{1}{n_f^2} \right)
\]

provided the constant \( k_e e^2/2a_0 \hbar c \) is equal to the experimentally determined Rydberg constant. Soon after Bohr demonstrated that these two quantities agree to within approximately 1%, this work was recognized as the crowning achievement of his new quantum theory of the hydrogen atom. Furthermore, Bohr showed that all the spectral series for hydrogen have a natural interpretation in his theory. The different series correspond to transitions to different final states characterized by the quantum number \( n_f \). Figure 42.8 shows the origin of these spectral series as transitions between energy levels.

Bohr extended his model for hydrogen to other elements in which all but one electron had been removed. These systems have the same structure as the hydrogen atom except that the nuclear charge is larger. Ionized elements such as He\(^+\), Li\(^{2+}\), and Be\(^{2+}\) were suspected to exist in hot stellar atmospheres, where atomic collisions frequently have enough energy to completely remove one or more atomic electrons. Bohr showed that many mysterious lines observed in the spectra of the Sun and several other stars could not be due to hydrogen but were correctly predicted by his theory if attributed to singly ionized helium. In general, the number of protons in the nucleus of an atom is called the atomic number of the element.
and is given the symbol $Z$. To describe a single electron orbiting a fixed nucleus of charge $+Ze$, Bohr’s theory gives

$$r_n = \left(\frac{n^2}{Z}\right)\frac{a_0}{Z}$$  \hspace{1cm} (42.18)

$$E_n = -\frac{k_e e^2}{2a_0}\left(\frac{Z^2}{n^2}\right) \quad n = 1, 2, 3, \ldots$$  \hspace{1cm} (42.19)

Although the Bohr theory was triumphant in its agreement with some experimental results on the hydrogen atom, it suffered from some difficulties. One of the first indications that the Bohr theory needed to be modified arose when improved spectroscopic techniques were used to examine the spectral lines of hydrogen. It was found that many of the lines in the Balmer and other series were not single lines at all. Instead, each was a group of lines spaced very close together. An additional difficulty arose when it was observed that in some situations certain single spectral lines were split into three closely spaced lines when the atoms were placed in a strong magnetic field. Efforts to explain these and other deviations from the Bohr model led to modifications in the theory and ultimately to a replacement theory that will be discussed in Section 42.4.

**Bohr’s Correspondence Principle**

In our study of relativity, we found that Newtonian mechanics is a special case of relativistic mechanics and is usable only for speeds much less than $c$. Similarly,

quantum physics agrees with classical physics when the difference between quantized levels becomes vanishingly small.

This principle, first set forth by Bohr, is called the **correspondence principle**.\(^2\)

For example, consider an electron orbiting the hydrogen atom with $n > 10000$. For such large values of $n$, the energy differences between adjacent levels approach zero; therefore, the levels are nearly continuous. Consequently, the classical model is reasonably accurate in describing the system for large values of $n$. According to the classical picture, the frequency of the light emitted by the atom is equal to the frequency of revolution of the electron in its orbit about the nucleus. Calculations show that for $n > 10000$, this frequency is different from that predicted by quantum mechanics by less than 0.015%.

**Quick Quiz 42.1** A hydrogen atom is in its ground state. Incident on the atom is a photon having an energy of 10.5 eV. What is the result? (a) The atom is excited to a higher allowed state. (b) The atom is ionized. (c) The photon passes by the atom without interaction.

**Quick Quiz 42.2** A hydrogen atom makes a transition from the $n = 3$ level to the $n = 2$ level. It then makes a transition from the $n = 2$ level to the $n = 1$ level. Which transition results in emission of the longer-wavelength photon? (a) the first transition (b) the second transition (c) neither transition because the wavelengths are the same for both
Use Equation 42.17 to obtain $\lambda$, with $n_i = 2$ and $n_f = 1$:

$$\frac{1}{\lambda} = R_H \left( \frac{1}{1^2} - \frac{1}{2^2} \right) = \frac{3R_H}{4}$$

$$\lambda = \frac{4}{3R_H} = \frac{4}{3(1.097 \times 10^{-7} \text{ m}^{-1})} = 1.22 \times 10^{-7} \text{ m} = 122 \text{ nm}$$

Use Equation 34.20 to find the frequency of the photon:

$$f = \frac{c}{\lambda} = \frac{3.00 \times 10^8 \text{ m/s}}{1.22 \times 10^{-7} \text{ m}} = 2.47 \times 10^{15} \text{ Hz}$$

(B) In interstellar space, highly excited hydrogen atoms called Rydberg atoms have been observed. Find the wavelength to which radio astronomers must tune to detect signals from electrons dropping from the $n = 273$ level to the $n = 272$ level.

Use Equation 42.17, this time with $n_i = 273$ and $n_f = 272$:

$$\frac{1}{\lambda} = R_H \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right) = R_H \left( \frac{1}{(272)^2} - \frac{1}{(273)^2} \right) = 9.88 \times 10^{-8} R_H$$

Solve for $\lambda$:

$$\lambda = \frac{1}{9.88 \times 10^{-8} R_H} = \frac{1}{(9.88 \times 10^{-8})(1.097 \times 10^7 \text{ m}^{-1})} = 0.922 \text{ m}$$

(C) What is the radius of the electron orbit for a Rydberg atom for which $n = 273$?

Use Equation 42.12 to find the radius of the orbit:

$$r_{273} = (273)^2 (0.052 \text{ nm}) = 3.94 \mu\text{m}$$

This radius is large enough that the atom is on the verge of becoming macroscopic!

(D) How fast is the electron moving in a Rydberg atom for which $n = 273$?

Solve Equation 42.8 for the electron’s speed:

$$v = \sqrt{\frac{k_e e^2}{m_e r}} = \sqrt{\frac{(8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)(1.60 \times 10^{-19} \text{ C})^2}{(9.11 \times 10^{-31} \text{ kg})(3.94 \times 10^{-8} \text{ m})}} = 8.01 \times 10^3 \text{ m/s}$$

WHAT IF? What if radiation from the Rydberg atom in part (B) is treated classically? What is the wavelength of radiation emitted by the atom in the $n = 273$ level?

Answer Classically, the frequency of the emitted radiation is that of the rotation of the electron around the nucleus.

Calculate this frequency using the period defined in Equation 4.15:

$$f = \frac{1}{T} = \frac{v}{2\pi r}$$

Substitute the radius and speed from parts (C) and (D):

$$f = \frac{8.02 \times 10^3 \text{ m/s}}{2\pi(3.94 \times 10^{-8} \text{ m})} = 3.24 \times 10^8 \text{ Hz}$$

Find the wavelength of the radiation from Equation 34.20:

$$\lambda = \frac{c}{f} = \frac{3.00 \times 10^8 \text{ m/s}}{3.24 \times 10^8 \text{ Hz}} = 0.927 \text{ m}$$

This value is about 0.5% different from the wavelength calculated in part (B). As indicated in the discussion of Bohr’s correspondence principle, this difference becomes even smaller for higher values of $n$. 
42.4 The Quantum Model of the Hydrogen Atom

In the preceding section, we described how the Bohr model views the electron as a particle orbiting the nucleus in nonradiating, quantized energy levels. This model combines both classical and quantum concepts. Although the model demonstrates excellent agreement with some experimental results, it cannot explain others. These difficulties are removed when a full quantum model involving the Schrödinger equation is used to describe the hydrogen atom.

The formal procedure for solving the problem of the hydrogen atom is to substitute the appropriate potential energy function into the Schrödinger equation, find solutions to the equation, and apply boundary conditions as we did for the particle in a box in Chapter 41. The potential energy function for the hydrogen atom is that due to the electrical interaction between the electron and the proton (see Section 25.3):

$$U(r) = -k_e \frac{e^2}{r}$$  \hspace{1cm} (42.20)

where $k_e$ is the Coulomb constant and $r$ is the radial distance from the proton (situated at $r = 0$) to the electron.

The mathematics for the hydrogen atom is more complicated than that for the particle in a box for two primary reasons: (1) the atom is three-dimensional, and (2) $U$ is not constant, but rather depends on the radial coordinate $r$. If the time-independent Schrödinger equation (Eq. 41.15) is extended to three-dimensional rectangular coordinates, the result is

$$-\frac{\hbar^2}{2m} \left( \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} \right) + U\psi = E\psi$$

It is easier to solve this equation for the hydrogen atom if rectangular coordinates are converted to spherical polar coordinates, an extension of the plane polar coordinates introduced in Section 3.1. In spherical polar coordinates, a point in space is represented by the three variables $r$, $\theta$, and $\phi$, where $r$ is the radial distance from the origin, $r = \sqrt{x^2 + y^2 + z^2}$. With the point represented at the end of a position vector $\vec{r}$ as shown in Figure 42.9, the angular coordinate $\theta$ specifies its angular position relative to the $z$ axis. Once that position vector is projected onto the $xy$ plane, the angular coordinate $\phi$ specifies the projection’s (and therefore the point’s) angular position relative to the $x$ axis.

The conversion of the three-dimensional time-independent Schrödinger equation for $\psi(x, y, z)$ to the equivalent form for $\psi(r, \theta, \phi)$ is straightforward but very tedious, so we omit the details. In Chapter 41, we separated the time dependence in the general wave function $\Psi$. In this case of the hydrogen atom, the three space variables in $\psi(r, \theta, \phi)$ can be similarly separated by writing the wave function as a product of functions of each single variable:

$$\psi(r, \theta, \phi) = R(r)f(\theta)g(\phi)$$

In this way, Schrödinger’s equation, which is a three-dimensional partial differential equation, can be transformed into three separate ordinary differential equations: one for $R(r)$, one for $f(\theta)$, and one for $g(\phi)$. Each of these functions is subject to boundary conditions. For example, $R(r)$ must remain finite as $r \to 0$ and $r \to \infty$; furthermore, $g(\phi)$ must have the same value as $g(\phi + 2\pi)$.

The potential energy function given in Equation 42.20 depends only on the radial coordinate $r$ and not on either of the angular coordinates; therefore, it appears only in the equation for $R(r)$. As a result, the equations for $\theta$ and $\phi$ are independent of the particular system and their solutions are valid for any system exhibiting rotation.

When the full set of boundary conditions is applied to all three functions, three different quantum numbers are found for each allowed state of the hydrogen atom.

---

one for each of the separate differential equations. These quantum numbers are restricted to integer values and correspond to the three independent degrees of freedom (three space dimensions).

The first quantum number, associated with the radial function \( R(r) \) of the full wave function, is called the \textbf{principal quantum number} and is assigned the symbol \( n \). The differential equation for \( R(r) \) leads to functions giving the probability of finding the electron at a certain radial distance from the nucleus. In Section 42.5, we will describe two of these radial wave functions. From the boundary conditions, the energies of the allowed states for the hydrogen atom are found to be related to \( n \) as follows:

\[
E_n = -\frac{\hbar^2}{2\mu a_0^2} \frac{1}{n^2} = -\frac{13.606 \text{ eV}}{n^2} \quad n = 1, 2, 3, \ldots
\]  \hspace{1cm} (42.21)

This result is in exact agreement with that obtained in the Bohr theory (Eqs. 42.13 and 42.14)! This agreement is \textit{remarkable} because the Bohr theory and the full quantum theory arrive at the result from completely different starting points.

The \textbf{orbital quantum number}, symbolized \( \ell \), comes from the differential equation for \( f(\theta) \) and is associated with the orbital angular momentum of the electron. The \textbf{orbital magnetic quantum number} \( m_\ell \) arises from the differential equation for \( g(\phi) \). Both \( \ell \) and \( m_\ell \) are integers. We will expand our discussion of these two quantum numbers in Section 42.6, where we also introduce a fourth (nonintegral) quantum number, resulting from a relativistic treatment of the hydrogen atom.

The application of boundary conditions on the three parts of the full wave function leads to important relationships among the three quantum numbers as well as certain restrictions on their values:

The values of \( n \) are integers that can range from 1 to \( \infty \).

The values of \( \ell \) are integers that can range from 0 to \( n - 1 \).

The values of \( m_\ell \) are integers that can range from \(-\ell \) to \( \ell \).

For example, if \( n = 1 \), only \( \ell = 0 \) and \( m_\ell = 0 \) are permitted. If \( n = 2 \), then \( \ell \) may be 0 or 1; if \( \ell = 0 \), then \( m_\ell = 0 \); but if \( \ell = 1 \), then \( m_\ell \) may be 0, 1, or \(-1 \). Table 42.1 summarizes the rules for determining the allowed values of \( \ell \) and \( m_\ell \) for a given \( n \).

For historical reasons, all states having the same principal quantum number are said to form a \textbf{shell}. Shells are identified by the letters K, L, M, \ldots , which designate the states for which \( n = 1, 2, 3, \ldots \). Likewise, all states having the same values of \( n \) and \( \ell \) are said to form a \textbf{subshell}. The letters \( s, p, d, f, g, h, \ldots \) are used to designate the subshells for which \( \ell = 0, 1, 2, 3, \ldots \). The state designated by \( 3p \), for example, has the quantum numbers \( n = 3 \) and \( \ell = 1 \); the \( 2s \) state has the quantum numbers \( n = 2 \) and \( \ell = 0 \). These notations are summarized in Tables 42.2 and 42.3 (page 1308).

States that violate the rules given in Table 42.1 do not exist. (They do not satisfy the boundary conditions on the wave function.) For instance, the \( 2d \) state, which

would have \( n = 2 \) and \( \ell = 2 \), cannot exist because the highest allowed value of \( \ell \) is \( n - 1 \), which in this case is 1. Therefore, for \( n = 2 \), the 2s and 2p states are allowed but 2d, 2f, . . . are not. For \( n = 3 \), the allowed subshells are 3s, 3p, and 3d.

Quick Quiz 42.3 How many possible subshells are there for the \( n = 4 \) level of hydrogen? (a) 5 (b) 4 (c) 3 (d) 2 (e) 1

Quick Quiz 42.4 When the principal quantum number is \( n = 5 \), how many different values of (a) \( \ell \) and (b) \( m_\ell \) are possible?

Example 42.2 The \( n = 2 \) Level of Hydrogen

For a hydrogen atom, determine the allowed states corresponding to the principal quantum number \( n = 2 \) and calculate the energies of these states.

Solution

Conceptualize Think about the atom in the \( n = 2 \) quantum state. There is only one such state in the Bohr theory, but our discussion of the quantum theory allows for more states because of the possible values of \( \ell \) and \( m_\ell \).

Categorize We evaluate the results using rules discussed in this section, so we categorize this example as a substitution problem.

From Table 42.1, we find that when \( n = 2 \), \( \ell \) can be 0 or 1. Find the possible values of \( m_\ell \) from Table 42.1:

- \( \ell = 0 \rightarrow m_\ell = 0 \)
- \( \ell = 1 \rightarrow m_\ell = -1, 0, \text{ or } 1 \)

Hence, we have one state, designated as the 2s state, that is associated with the quantum numbers \( n = 2, \ell = 0, \text{ and } m_\ell = 0 \), and we have three states, designated as 2p states, for which the quantum numbers are \( n = 2, \ell = 1, \text{ and } m_\ell = -1; n = 2, \ell = 1, \text{ and } m_\ell = 0; \) and \( n = 2, \ell = 1, \text{ and } m_\ell = 1 \).

Find the energy for all four of these states with \( n = 2 \) from Equation 42.21:

\[ E_2 = -\frac{13.606 \text{ eV}}{2^2} = -3.401 \text{ eV} \]

42.5 The Wave Functions for Hydrogen

Because the potential energy of the hydrogen atom depends only on the radial distance \( r \) between nucleus and electron, some of the allowed states for this atom can be represented by wave functions that depend only on \( r \). For these states, \( f(\theta) \) and \( g(\phi) \) are constants. The simplest wave function for hydrogen is the one that describes the 1s state and is designated \( \psi_{1s}(r) \):

\[ \psi_{1s}(r) = \frac{1}{\sqrt{\pi a_0^3}} e^{-r/a_0} \]  

(42.22)

where \( a_0 \) is the Bohr radius. (In Problem 26, you can verify that this function satisfies the Schrödinger equation.) Note that \( \psi_{1s} \) approaches zero as \( r \) approaches \( \infty \) and is normalized as presented (see Eq. 41.7). Furthermore, because \( \psi_{1s} \) depends only on \( r \), it is spherically symmetric. This symmetry exists for all \( s \) states.

Recall that the probability of finding a particle in any region is equal to an integral of the probability density \( |\psi|^2 \) for the particle over the region. The probability density for the 1s state is

\[ |\psi_{1s}|^2 = \left( \frac{1}{\pi a_0^3} \right) e^{-2r/a_0} \]  

(42.23)
Because we imagine the nucleus to be fixed in space at \( r = 0 \), we can assign this probability density to the question of locating the electron. According to Equation 41.3, the probability of finding the electron in a volume element \( dV \) is \( |\psi|^2 dV \). It is convenient to define the radial probability density function \( P(r) \) as the probability per unit radial length of finding the electron in a spherical shell of radius \( r \) and thickness \( dr \). Therefore, \( P(r) \ dr \) is the probability of finding the electron in this shell. The volume \( dV \) of such an infinitesimally thin shell equals its surface area \( 4\pi r^2 \) multiplied by the shell thickness \( dr \) (Fig. 42.10), so we can write this probability as

\[
P(r) \ dr = |\psi|^2 dV = |\psi|^2 4\pi r^2 \ dr
\]

Therefore, the radial probability density function for an \( s \) state is

\[
P_s(r) = 4\pi r^2 |\psi|^2
\]  

(42.24)

Substituting Equation 42.23 into Equation 42.24 gives the radial probability density function for the hydrogen atom in its ground state:

\[
P_{1s}(r) = \left( \frac{4r^2}{a_0^3} \right) e^{-2r/a_0}
\]  

(42.25)

A plot of the function \( P_{1s}(r) \) versus \( r \) is presented in Figure 42.11a. The peak of the curve corresponds to the most probable value of \( r \) for this particular state. We show in Example 42.3 that this peak occurs at the Bohr radius, the radial position of the electron when the hydrogen atom is in its ground state in the Bohr theory, another remarkable agreement between the Bohr theory and the quantum theory.

According to quantum mechanics, the atom has no sharply defined boundary as suggested by the Bohr theory. The probability distribution in Figure 42.11a suggests that the charge of the electron can be modeled as being extended throughout a region of space, commonly referred to as an electron cloud. Figure 42.11b shows the probability density of the electron in a hydrogen atom in the \( 1s \) state as a function of position in the \( xy \) plane. The darkness of the blue color corresponds to the value of the probability density. The darkest portion of the distribution appears at \( r = a_0 \), corresponding to the most probable value of \( r \) for the electron.

**Example 42.3 The Ground State of Hydrogen**

(A) Calculate the most probable value of \( r \) for an electron in the ground state of the hydrogen atom.
42.3 continued

**Solution**

**Conceptualize** Do not imagine the electron in orbit around the proton as in the Bohr theory of the hydrogen atom. Instead, imagine the charge of the electron spread out in space around the proton in an electron cloud with spherical symmetry.

**Categorize** Because the statement of the problem asks for the “most probable value of \( r \),” we categorize this example as a problem in which the quantum approach is used. (In the Bohr atom, the electron moves in an orbit with an exact value of \( r \).

**Analyze** The most probable value of \( r \) corresponds to the maximum in the plot of \( P_{1s}(r) \) versus \( r \). We can evaluate the most probable value of \( r \) by setting \( dP_{1s}/dr = 0 \) and solving for \( r \):

Differentiate Equation 42.25 and set the result equal to zero:

\[
\frac{dP_{1s}}{dr} = \frac{d}{dr} \left[ \frac{4r^2}{a_0^3} e^{-2r/a_0} \right] = 0
\]

\[
e^{-2r/a_0} \frac{d}{dr} \left( \frac{4r^2}{a_0^3} \right) + \frac{4r^2}{a_0^3} \frac{d}{dr} \left( e^{-2r/a_0} \right) = 0
\]

\[
2r e^{-2r/a_0} + r^2(-2/a_0) e^{-2r/a_0} = 0
\]

\[
1 - \frac{r}{a_0} = 0 \rightarrow r = a_0
\]

**Finalize** The most probable value of \( r \) is the Bohr radius! Equation (1) is also satisfied at \( r = 0 \) and as \( r \to \infty \). These points are locations of the minimum probability, which is equal to zero as seen in Figure 42.11a.

**(B)** Calculate the probability that the electron in the ground state of hydrogen will be found outside the Bohr radius.

**Solution**

**Analyze** The probability is found by integrating the radial probability density function \( P_{1s}(r) \) for this state from the Bohr radius \( a_0 \) to \( \infty \):

Set up this integral using Equation 42.25:

\[
P = \int_{a_0}^{\infty} P_{1s}(r) \, dr = \frac{4}{a_0^3} \int_{a_0}^{\infty} r^2 e^{-2r/a_0} \, dr
\]

Put the integral in dimensionless form by changing variables from \( r \) to \( z = 2r/a_0 \) noting that \( z = 2 \) when \( r = a_0 \) and that \( dr = (a_0/2) \, dz \):

\[
P = \frac{4}{a_0^3} \int_{2}^{\infty} \left( \frac{z a_0}{2} \right)^2 \, e^{-z} \, \left( \frac{a_0}{2} \right) \, dz = \frac{1}{2} \int_{2}^{\infty} z^2 e^{-z} \, dz
\]

Evaluate the integral using partial integration (see Appendix B.7):

\[
P = -\left[ \frac{1}{2} (z^2 + 2z + 2) e^{-z} \right]_{2}^{\infty} = 0 - \frac{1}{2} \left( 4 + 4 + 2 \right) e^{-2} = 0 - \frac{5 e^{-2}}{2} = 0.677 \text{ or } 67.7\%.
\]

**Finalize** This probability is larger than 50%. The reason for this value is the asymmetry in the radial probability density function (Fig. 42.11a), which has more area to the right of the peak than to the left.

**What if** What if you were asked for the average value of \( r \) for the electron in the ground state rather than the most probable value?

**Answer** The average value of \( r \) is the same as the expectation value for \( r \):

Use Equation 42.25 to evaluate the average value of \( r \):

\[
r_{avg} = \langle r \rangle = \int_{a_0}^{\infty} r P(r) \, dr = \int_{a_0}^{\infty} r \left( \frac{4r^2}{a_0^3} \right) e^{-2r/a_0} \, dr
\]

\[
= \frac{4}{a_0^3} \int_{a_0}^{\infty} r^2 e^{-2r/a_0} \, dr
\]
Evaluate the integral with the help of the first integral listed in Table B.6 in Appendix B:

\[ r_{\text{avg}} = \left( \frac{4}{a_0} \right) \left( \frac{3!}{(2/a_0)^4} \right) = \frac{3}{2} a_0 \]

Again, the average value is larger than the most probable value because of the asymmetry in the wave function as seen in Figure 42.11a.

The next-simplest wave function for the hydrogen atom is the one corresponding to the 2s state \((n = 2, \ell = 0)\). The normalized wave function for this state is

\[
\psi_{2s}(r) = \frac{1}{4\sqrt{2\pi}} \left( \frac{1}{a_0} \right)^{3/2} \left( 2 - \frac{r}{a_0} \right) e^{-r/2a_0}
\]

(42.26)

Again notice that \(\psi_{2s}\) depends only on \(r\) and is spherically symmetric. The energy corresponding to this state is \(E_2 = -(13.606/4)\) eV = \(-3.401\) eV. This energy level represents the first excited state of hydrogen. A plot of the radial probability density function for this state in comparison to the 1s state is shown in Figure 42.12. The plot for the 2s state has two peaks. In this case, the most probable value corresponds to that value of \(r\) that has the highest value of \(P(r)\). An electron in the 2s state would be much farther from the nucleus (on the average) than an electron in the 1s state.

### 42.6 Physical Interpretation of the Quantum Numbers

The principal quantum number \(n\) of a particular state in the hydrogen atom determines the energy of the atom according to Equation 42.21. Now let’s see what the other quantum numbers in our atomic model correspond to physically.

#### The Orbital Quantum Number \(\ell\)

We begin this discussion by returning briefly to the Bohr model of the atom. If the electron moves in a circle of radius \(r\), the magnitude of its angular momentum relative to the center of the circle is \(L = m_v r\). The direction of \(L\) is perpendicular to the plane of the circle and is given by a right-hand rule. According to classical physics, the magnitude \(L\) of the orbital angular momentum can have any value. The Bohr model of hydrogen, however, postulates that the magnitude of the angular momentum of the electron is restricted to multiples of \(\hbar\); that is, \(L = n\hbar\). This model must be modified because it predicts (incorrectly) that the ground state of hydrogen has one unit of angular momentum. Furthermore, if \(L\) is taken to be zero in the Bohr model, the electron must be pictured as a particle oscillating along a straight line through the nucleus, which is a physically unacceptable situation.

These difficulties are resolved with the quantum-mechanical model of the atom, although we must give up the convenient mental representation of an electron orbiting in a well-defined circular path. Despite the absence of this representation, the atom does indeed possess an angular momentum and it is still called orbital angular momentum. According to quantum mechanics, an atom in a state whose principal quantum number is \(n\) can take on the following discrete values of the magnitude of the orbital angular momentum:

\[
L = \sqrt{\ell(\ell + 1)} \hbar \quad \ell = 0, 1, 2, \ldots, n - 1
\]

(42.27)

\(\hbar\) is Planck’s constant divided by 2\(\pi\).

Equation 42.27 is a direct result of the mathematical solution of the Schrödinger equation and the application of angular boundary conditions. This development, however, is beyond the scope of this book.
Given these allowed values of \( \ell \), we see that \( L = 0 \) (corresponding to \( \ell = 0 \)) is an acceptable value of the magnitude of the angular momentum. That \( L \) can be zero in this model serves to point out the inherent difficulties in any attempt to describe results based on quantum mechanics in terms of a purely particle-like (classical) model. In the quantum-mechanical interpretation, the electron cloud for the \( L = 0 \) state is spherically symmetric and has no fundamental rotation axis.

**The Orbital Magnetic Quantum Number \( m_\ell \)**

Because angular momentum is a vector, its direction must be specified. Recall from Chapter 29 that a current loop has a corresponding magnetic moment \( \vec{\mu} = I \vec{A} \) (Eq. 29.15), where \( I \) is the current in the loop and \( \vec{A} \) is a vector perpendicular to the loop whose magnitude is the area of the loop. Such a moment placed in a magnetic field \( \vec{B} \) interacts with the field. Suppose a weak magnetic field applied along the \( z \) axis defines a direction in space. According to classical physics, the energy of the loop–field system depends on the direction of the magnetic moment of the loop with respect to the magnetic field as described by Equation 29.18, \( U_B = -\vec{\mu} \cdot \vec{B} \). Any energy between \(-\mu B \) and \(+\mu B \) is allowed by classical physics.

In the Bohr theory, the circulating electron represents a current loop. In the quantum-mechanical approach to the hydrogen atom, we abandon the circular orbit viewpoint of the Bohr theory, but the atom still possesses an orbital angular momentum. Therefore, there is some sense of rotation of the electron around the nucleus and a magnetic moment is present due to this angular momentum.

As mentioned in Section 42.3, spectral lines from some atoms are observed to split into groups of three closely spaced lines when the atoms are placed in a magnetic field. Suppose the hydrogen atom is located in a magnetic field. According to quantum mechanics, there are discrete directions allowed for the magnetic moment vector \( \vec{\mu} \) with respect to the magnetic field vector \( \vec{B} \). This situation is very different from that in classical physics, in which all directions are allowed.

Because the magnetic moment \( \vec{\mu} \) of the atom can be related to the angular momentum vector \( \vec{L} \), the discrete directions of \( \vec{\mu} \) translate to the direction of \( \vec{L} \) being quantized. This quantization means that \( L_z \) (the projection of \( \vec{L} \) along the \( z \) axis) can have only discrete values. The orbital magnetic quantum number \( m_\ell \) specifies the allowed values of the \( z \) component of the orbital angular momentum according to the expression

\[
L_z = m_\ell \hbar \quad (42.28)
\]

The quantization of the possible orientations of \( \vec{L} \) with respect to an external magnetic field is often referred to as space quantization.

Let’s look at the possible magnitudes and orientations of \( \vec{L} \) for a given value of \( \ell \). Recall that \( m_\ell \) can have values ranging from \(-\ell \) to \( \ell \). If \( \ell = 0 \), then \( L = 0 \); the only allowed value of \( m_\ell \) is \( m_\ell = 0 \) and \( L_z = 0 \). If \( \ell = 1 \), then \( L = \sqrt{2} \hbar \) from Equation 42.27. The possible values of \( m_\ell \) are \(-1, 0, \) and \( 1 \), so Equation 42.28 tells us that \( L_z \) may be \(-\hbar, 0, \) or \( \hbar \). If \( \ell = 2 \), the magnitude of the orbital angular momentum is \( \sqrt{6} \hbar \). The value of \( m_\ell \) can be \(-2, -1, 0, 1, \) or \( 2 \), corresponding to \( L_z \) values of \(-2\hbar, -\hbar, 0, \) \( \hbar, \) or \( 2\hbar \), and so on.

Figure 42.13a shows a vector model that describes space quantization for the case \( \ell = 2 \). Notice that \( \vec{L} \) can never be aligned parallel or antiparallel to \( \vec{B} \) because the maximum value of \( L_z \) is \( \ell \hbar \), which is less than the magnitude of the angular momentum \( L = \sqrt{\ell(\ell + 1)} \hbar \). The angular momentum vector \( \vec{L} \) is allowed to be perpendicular to \( \vec{B} \), which corresponds to the case of \( L_z = 0 \) and \( \ell = 0 \).

---

6See Equation 30.22 for this relationship as derived from a classical viewpoint. Quantum mechanics arrives at the same result.

7As with Equation 42.27, the relationship expressed in Equation 42.28 arises from the solution to the Schrödinger equation and application of boundary conditions.
42.6 Physical Interpretation of the Quantum Numbers

The vector $\mathbf{L}$ does not point in one specific direction. If $\mathbf{L}$ were known exactly, all three components $L_x$, $L_y$, and $L_z$ would be specified, which is inconsistent with an angular momentum version of the uncertainty principle. How can the magnitude and $z$ component of a vector be specified, but the vector not be completely specified? To answer, imagine that $L_x$ and $L_y$ are completely unspecified so that $\mathbf{L}$ lies anywhere on the surface of a cone that makes an angle $\theta$ with the $z$ axis as shown in Figure 42.13b. From the figure, we see that $\theta$ is also quantized and that its values are specified through the relationship

$$\cos \theta = \frac{L_z}{L} = \frac{m_\ell}{\sqrt{\ell(\ell + 1)}} \tag{42.29}$$

If the atom is placed in a magnetic field, the energy $U_B = -\mathbf{\mu} \cdot \mathbf{B}$ is additional energy for the atom–field system beyond that described in Equation 42.21. Because the directions of $\mathbf{\mu}$ are quantized, there are discrete total energies for the system corresponding to different values of $m_\ell$. Figure 42.14a shows a transition between two atomic levels in the absence of a magnetic field. In Figure 42.14b, a magnetic field is present. The allowed projections on the $z$ axis of the orbital angular momentum $\mathbf{L}$ are integer multiples of $\hbar$.

**Figure 42.13** A vector model for $\ell = 2$.

**Figure 42.14** The Zeeman effect. (a) Energy levels for the ground and first excited states of a hydrogen atom. (b) When the atom is immersed in a magnetic field $\mathbf{B}$, the state with $\ell = 1$ splits into three states, giving rise to emission lines at $f_0$, $f_0 + \Delta f$, and $f_0 - \Delta f$, where $\Delta f$ is the frequency shift of the emission caused by the magnetic field.
field is applied and the upper level, with $\ell = 1$, splits into three levels corresponding to the different directions of $\mathbf{\hat{z}}$. There are now three possible transitions from the $\ell = 1$ subshell to the $\ell = 0$ subshell. Therefore, in a collection of atoms, there are atoms in all three states and the single spectral line in Figure 42.14a splits into three spectral lines. This phenomenon is called the Zeeman effect.

The Zeeman effect can be used to measure extraterrestrial magnetic fields. For example, the splitting of spectral lines in light from hydrogen atoms in the surface of the Sun can be used to calculate the magnitude of the magnetic field at that location. The Zeeman effect is one of many phenomena that cannot be explained with the Bohr model but are successfully explained by the quantum model of the atom.

### Example 42.4  Space Quantization for Hydrogen

Consider the hydrogen atom in the $\ell = 3$ state. Calculate the magnitude of $\mathbf{L}$, the allowed values of $L_z$, and the corresponding angles $\theta$ that $\mathbf{L}$ makes with the $z$ axis.

#### Solution

**Conceptualize**  Consider Figure 42.13a, which is a vector model for $\ell = 2$. Draw such a vector model for $\ell = 3$ to help with this problem.

**Categorize**  We evaluate results using equations developed in this section, so we categorize this example as a substitution problem.

Calculate the magnitude of the orbital angular momentum using Equation 42.27:

$$ L = \sqrt{\ell(\ell + 1)} \hbar = \sqrt{3(3 + 1)} \hbar = 2\sqrt{3} \hbar $$

Calculate the allowed values of $L_z$ using Equation 42.28 with $m_\ell = -3, -2, -1, 0, 1, 2, \text{ and } 3$:

$$ L_z = \{-3\hbar, -2\hbar, -\hbar, 0, \hbar, 2\hbar, 3\hbar\} $$

Calculate the allowed values of $\cos \theta$ using Equation 42.29:

$$ \cos \theta = \frac{\pm 3}{2\sqrt{3}} = \pm 0.866 \quad \cos \theta = \frac{\pm 2}{2\sqrt{3}} = \pm 0.577 \quad \cos \theta = \frac{\pm 1}{2\sqrt{3}} = \pm 0.289 \quad \cos \theta = \frac{0}{2\sqrt{3}} = 0 $$

Find the angles corresponding to these values of $\cos \theta$:  $\theta = 30.0^\circ, 54.7^\circ, 73.2^\circ, 90.0^\circ, 107^\circ, 125^\circ, 150^\circ$

**What if?**  What if the value of $\ell$ is an arbitrary integer? For an arbitrary value of $\ell$, how many values of $m_\ell$ are allowed?

**Answer**  For a given value of $\ell$, the values of $m_\ell$ range from $-\ell$ to $+\ell$ in steps of 1. Therefore, there are $2\ell$ nonzero values of $m_\ell$ (specifically, $\pm 1, \pm 2, \ldots, \pm \ell$). In addition, one more value of $m_\ell = 0$ is possible, for a total of $2\ell + 1$ values of $m_\ell$. This result is critical in understanding the results of the Stern–Gerlach experiment described below with regard to spin.

### The Spin Magnetic Quantum Number $m_s$

The three quantum numbers $n$, $\ell$, and $m_\ell$ discussed so far are generated by applying boundary conditions to solutions of the Schrödinger equation, and we can assign a physical interpretation to each quantum number. Let’s now consider electron spin, which does not come from the Schrödinger equation.

In Example 42.2, we found four quantum states corresponding to $n = 2$. In reality, however, eight such states occur. The additional four states can be explained by requiring a fourth quantum number for each state, the spin magnetic quantum number $m_s$.

The need for this new quantum number arises because of an unusual feature observed in the spectra of certain gases, such as sodium vapor. Close examination of one prominent line in the emission spectrum of sodium reveals that the
This phenomenon is a Zeeman effect for spin and is identical in nature to the Zeeman effect for orbital angular momentum discussed before Example 42.4 except that no external magnetic field is required. The magnetic field for this Zeeman effect is internal to the atom and arises from the relative motion of the electron and the nucleus.

To describe this new quantum number, it is convenient (but technically incorrect) to imagine the electron spinning about its axis as it orbits the nucleus as described in Section 30.6. As illustrated in Figure 42.15, only two directions exist for the electron spin. If the direction of spin is as shown in Figure 42.15a, the electron is said to have spin up. If the direction of spin is as shown in Figure 42.15b, the electron is said to have spin down. In the presence of a magnetic field, the energy associated with the electron is slightly different for the two spin directions. This energy difference accounts for the sodium doublet.

The classical description of electron spin—as resulting from a spinning electron—is incorrect. More recent theory indicates that the electron is a point particle, without spatial extent. Therefore, the electron is not modeled as a rigid object and cannot be considered to be spinning. Despite this conceptual difficulty, all experimental evidence supports the idea that an electron does have some intrinsic angular momentum that can be described by the spin magnetic quantum number. Paul Dirac (1902–1984) showed that this fourth quantum number originates in the relativistic properties of the electron.

In 1921, Otto Stern (1888–1969) and Walter Gerlach (1889–1979) performed an experiment that demonstrated space quantization. Their results, however, were not in quantitative agreement with the atomic theory that existed at that time. In their experiment, a beam of silver atoms sent through a nonuniform magnetic field was split into two discrete components (Fig. 42.16). Stern and Gerlach repeated the experiment using other atoms, and in each case the beam split into two or more components. The classical argument is as follows. If the $z$ direction is chosen to be the direction of the maximum nonuniformity of $\mathbf{B}$, the net magnetic force on the atoms is along the $z$ axis and is proportional to the component of the magnetic moment $\mathbf{\mu}$ of the atom in the $z$ direction. Classically, $\mathbf{\mu}$ can have any orientation, so the deflected beam should be spread out continuously. According to quantum mechanics, however, the deflected beam has an integral number of discrete components and the number of components determines the number of possible values of $\mu_z$. Therefore, because the Stern–Gerlach experiment showed split beams, space quantization was at least qualitatively verified.

**Pitfall Prevention 42.5**

**The Electron Is Not Spinning**

Although the concept of a spinning electron is conceptually useful, it should not be taken literally. The spin of the Earth is a mechanical rotation. On the other hand, electron spin is a purely quantum effect that gives the electron an angular momentum as if it were physically spinning.
Atomic Physics

For the moment, let’s assume the magnetic moment of the atom is due to the orbital angular momentum. Because \( m_z \) is proportional to \( m_l \), the number of possible values of \( m_z \) is \( 2\ell + 1 \) as found in the What If? section of Example 42.4. Furthermore, because \( \ell \) is an integer, the number of values of \( m_z \) is always odd. This prediction is not consistent with Stern and Gerlach’s observation of two components (an even number) in the deflected beam of silver atoms. Hence, either quantum mechanics is incorrect or the model is in need of refinement.

In 1927, T. E. Phipps and J. B. Taylor repeated the Stern–Gerlach experiment using a beam of hydrogen atoms. Their experiment was important because it involved an atom containing a single electron in its ground state, for which the quantum theory makes reliable predictions. Recall that \( m_s = 0 \) for hydrogen in its ground state, so \( m_z = 0 \). Therefore, we would not expect the beam to be deflected by the magnetic field at all because the magnetic moment \( \mu \) of the atom is zero. The beam in the Phipps–Taylor experiment, however, was again split into two components! On the basis of that result, we must conclude that something other than the electron’s orbital motion is contributing to the atomic magnetic moment.

As we learned earlier, Goudsmit and Uhlenbeck had proposed that the electron has an intrinsic angular momentum, spin, apart from its orbital angular momentum. In other words, the total angular momentum of the electron in a particular electronic state contains both an orbital contribution \( \mathbf{L} \) and a spin contribution \( \mathbf{S} \).

The Phipps–Taylor result confirmed the hypothesis of Goudsmit and Uhlenbeck. In 1929, Dirac used the relativistic form of the total energy of a system to solve the relativistic wave equation for the electron in a potential well. His analysis confirmed the fundamental nature of electron spin. (Spin, like mass and charge, is an intrinsic property of a particle, independent of its surroundings.) Furthermore, the analysis showed that electron spin\(^9\) can be described by a single quantum number \( s \), whose value can be only \( s = \frac{1}{2} \). The spin angular momentum of the electron never changes. This notion contradicts classical laws, which dictate that a rotating charge slows down in the presence of an applied magnetic field because of the Faraday emf that accompanies the changing field (Chapter 31). Furthermore, if the electron is viewed as a spinning ball of charge subject to classical laws, parts of the electron near its surface would be rotating with speeds exceeding the speed of light. Therefore, the classical picture must not be pressed too far; ultimately, spin of an electron is a quantum entity defying any simple classical description.

Because spin is a form of angular momentum, it must follow the same quantum rules as orbital angular momentum. In accordance with Equation 42.27, the magnitude of the spin angular momentum \( \mathbf{S} \) for the electron is

\[
S = \sqrt{s(s + 1)} \hbar = \frac{\sqrt{3}}{2} \hbar
\]  

(42.30)

Like orbital angular momentum \( \mathbf{L} \), spin angular momentum \( \mathbf{S} \) exhibits space quantization as described in Figure 42.17. The spin vector \( \mathbf{S} \) can have two orientations relative to a \( z \) axis, specified by the spin magnetic quantum number \( m_s \). Similar to Equation 42.28 for orbital angular momentum, the \( z \) component of spin angular momentum is

\[
S_z = m_s \hbar = \pm \frac{1}{2} \hbar
\]  

(42.31)

The two values \( \pm \hbar/2 \) for \( S_z \) correspond to the two possible orientations for \( \mathbf{S} \) shown in Figure 42.17. The value \( m_s = +\frac{1}{2} \) refers to the spin-up case, and \( m_s = -\frac{1}{2} \) refers to the spin-down case. Notice that Equations 42.30 and 42.31 do not allow the spin vector to lie along the \( z \) axis. The actual direction of \( \mathbf{S} \) is at a relatively large angle with respect to the \( z \) axis as shown in Figures 42.15 and 42.17.

\(^9\)Scientists often use the word spin when referring to the spin angular momentum quantum number. For example, it is common to say, “The electron has a spin of one half.”
As discussed in the What If? feature of Example 42.4, there are \(2\ell + 1\) possible values of \(m_\ell\) for orbital angular momentum. Similarly, for spin angular momentum, there are \(2s + 1\) values of \(m_s\). For a spin of \(s = \frac{1}{2}\), the number of values of \(m_s\) is \(2s + 1 = 2\). These two possibilities for \(m_s\) lead to the splitting of the beams into two components in the Stern–Gerlach and Phipps–Taylor experiments.

The spin magnetic moment \(\vec{\mu}_{\text{spin}}\) of the electron is related to its spin angular momentum \(\vec{S}\) by the expression

\[
\vec{\mu}_{\text{spin}} = -\frac{e}{m_e} \vec{S}
\]

(42.32)

where \(e\) is the electronic charge and \(m_e\) is the mass of the electron. Because \(S_z = \pm \frac{1}{2}h\), the \(z\) component of the spin magnetic moment can have the values

\[
\vec{\mu}_{\text{spin},z} = \pm \frac{e\hbar}{2m_e}
\]

(42.33)

As we learned in Section 30.6, the quantity \(e\hbar/2m_e\) is the Bohr magneton \(\mu_B = 9.27 \times 10^{-24}\) J/T. The ratio of magnetic moment to angular momentum is twice as great for spin angular momentum (Eq. 42.32) as it is for orbital angular momentum (Eq. 30.22). The factor of 2 is explained in a relativistic treatment first carried out by Dirac.

Today, physicists explain the Stern–Gerlach and Phipps–Taylor experiments as follows. The observed magnetic moments for both silver and hydrogen are due to spin angular momentum only, with no contribution from orbital angular momentum. In the Phipps–Taylor experiment, the single electron in the hydrogen atom has its electron spin quantized in the magnetic field in such a way that the \(z\) component of spin angular momentum is either \(\frac{1}{2}\hbar\) or \(-\frac{1}{2}\hbar\), corresponding to \(m_s = \pm \frac{1}{2}\). Electrons with spin \(\frac{1}{2}\) are deflected downward, and those with spin \(-\frac{1}{2}\) are deflected upward. In the Stern–Gerlach experiment, 46 of a silver atom’s 47 electrons are in filled subshells with paired spins. Therefore, these 46 electrons have a net zero contribution to both orbital and spin angular momentum for the atom. The angular momentum of the atom is due to only the 47th electron. This electron lies in the 5s subshell, so there is no contribution from orbital angular momentum. As a result, the silver atoms have angular momentum due to just the spin of one electron and behave in the same way in a nonuniform magnetic field as the hydrogen atoms in the Phipps–Taylor experiment.

The Stern–Gerlach experiment provided two important results. First, it verified the concept of space quantization. Second, it showed that spin angular momentum exists, even though this property was not recognized until four years after the experiments were performed.

As mentioned earlier, there are eight quantum states corresponding to \(n = 2\) in the hydrogen atom, not four as found in Example 42.2. Each of the four states in Example 42.2 is actually two states because of the two possible values of \(m_s\). Table 42.4 shows the quantum numbers corresponding to these eight states.

Figure 42.17 Spin angular momentum \(\vec{S}\) exhibits space quantization. This figure shows the two allowed orientations of the spin angular momentum vector \(\vec{S}\) and the spin magnetic moment \(\vec{\mu}_{\text{spin}}\) for a spin-\(\frac{1}{2}\) particle, such as the electron.
Chapter 42  Atomic Physics

42.7 The Exclusion Principle and the Periodic Table

We have found that the state of a hydrogen atom is specified by four quantum numbers: \( n, \ell, m_c, \) and \( m_s \). As it turns out, the number of states available to other atoms may also be predicted by this same set of quantum numbers. In fact, these four quantum numbers can be used to describe all the electronic states of an atom, regardless of the number of electrons in its structure.

For our discussion of atoms with many electrons, it is often easiest to assign the quantum numbers to the electrons in the atom as opposed to the entire atom. An obvious question that arises here is, “How many electrons can be in a particular quantum state?” Pauli answered this important question in 1925, in a statement known as the exclusion principle:

No two electrons can ever be in the same quantum state; therefore, no two electrons in the same atom can have the same set of quantum numbers.

If this principle were not valid, an atom could radiate energy until every electron in the atom is in the lowest possible energy state and therefore the chemical behavior of the elements would be grossly modified. Nature as we know it would not exist.

In reality, we can view the electronic structure of complex atoms as a succession of filled levels increasing in energy. As a general rule, the order of filling of an atom’s subshells is as follows. Once a subshell is filled, the next electron goes into the lowest-energy vacant subshell. We can understand this behavior by recognizing that if the atom were not in the lowest energy state available to it, it would radiate energy until it reached this state. This tendency of a quantum system to achieve the lowest energy state is consistent with the second law of thermodynamics discussed in Chapter 22. The entropy of the Universe is increased by the system emitting photons, so that energy is spread out over a larger volume of space.

Before we discuss the electronic configuration of various elements, it is convenient to define an orbital as the atomic state characterized by the quantum numbers \( n, \ell, \) and \( m_c \). The exclusion principle tells us that only two electrons can be present in any orbital. One of these electrons has a spin magnetic quantum number \( m_s = +\frac{1}{2} \), and the other has \( m_s = -\frac{1}{2} \). Because each orbital is limited to two electrons, the number of electrons that can occupy the various shells is also limited.

Table 42.5 shows the allowed quantum states for an atom up to \( n = 3 \). The arrows pointing upward indicate an electron described by \( m_s = +\frac{1}{2} \), and those pointing downward indicate that \( m_s = -\frac{1}{2} \). The \( n = 1 \) shell can accommodate only two electrons because \( m_s = 0 \) means that only one orbital is allowed. (The three quantum numbers describing this orbital are \( n = 1, \ell = 0, \) and \( m_c = 0 \).) The \( n = 2 \) shell has two subshells, one for \( \ell = 0 \) and one for \( \ell = 1 \). The \( \ell = 0 \) subshell is limited to two electrons because \( m_c = 0 \). The \( \ell = 1 \) subshell has three allowed orbitals, corresponding to \( m_c = 1, 0, \) and \( -1 \). Because each orbital can accommodate two electrons, the \( \ell = 1 \) subshell can hold six electrons. Therefore, the \( n = 2 \) shell can contain eight electrons as shown in Table 42.4. The \( n = 3 \) shell has three subshells \( (\ell = 0, 1, 2) \) and nine orbitals, accommodating up to 18 electrons. In general, each shell can accommodate up to \( 2n^2 \) electrons.

The exclusion principle can be illustrated by examining the electronic arrangement in a few of the lighter atoms. The atomic number $Z$ of any element is the number of protons in the nucleus of an atom of that element. A neutral atom of that element has Z electrons. Hydrogen ($Z = 1$) has only one electron, which, in the ground state of the atom, can be described by either of two sets of quantum numbers $n$, $\ell$, $m_z$: 1, 0, 0, or 1, 0, $-\frac{1}{2}$. This electronic configuration is often written $1s^1$. The notation $1s^1$ refers to a state for which $n = 1$ and $\ell = 0$, and the superscript indicates that one electron is present in the $s$ subshell.

Helium ($Z = 2$) has two electrons. In the ground state, their quantum numbers are 1, 0, 0, $\frac{1}{2}$ and 1, 0, 0, $-\frac{1}{2}$. No other possible combinations of quantum numbers exist for this level, and we say that the K shell is filled. This electronic configuration is written $1s^2$.

Lithium ($Z = 3$) has three electrons. In the ground state, two of them are in the $1s$ subshell. The third is in the $2s$ subshell because this subshell is slightly lower in energy than the $2p$ subshell. Hence, the electronic configuration for lithium is $1s^22s^1$.

The electronic configurations of lithium and the next several elements are provided in Figure 42.18. The electronic configuration of beryllium ($Z = 4$), with its four electrons, is $1s^22s^2$, and boron ($Z = 5$) has a configuration of $1s^22s^22p^1$. The $2p$ electron in boron may be described by any of the six equally probable sets of quantum numbers listed in Table 42.4. In Figure 42.18, we show this electron in the leftmost $2p$ box with spin up, but it is equally likely to be in any $2p$ box with spin either up or down.

Carbon ($Z = 6$) has six electrons, giving rise to a question concerning how to assign the two $2p$ electrons. Do they go into the same orbital with paired spins ($\uparrow\downarrow$), or do they occupy different orbitals with unpaired spins ($\uparrow\downarrow$)? Experimental data show that the most stable configuration (that is, the one with the lowest energy) is the latter, in which the spins are unpaired. Hence, the two $2p$ electrons in carbon and the three $2p$ electrons in nitrogen ($Z = 7$) have unpaired spins as

To a first approximation, energy depends only on the quantum number $n$, as we have discussed. Because of the effect of the electronic charge shielding the nuclear charge, however, energy depends on $\ell$ also in multielectron atoms. We shall discuss these shielding effects in Section 42.8.
Figure 42.18 shows. The general rule that governs such situations, called **Hund’s rule**, states that

when an atom has orbitals of equal energy, the order in which they are filled by electrons is such that a maximum number of electrons have unpaired spins.

Some exceptions to this rule occur in elements having subshells that are close to being filled or half-filled.

In 1871, long before quantum mechanics was developed, the Russian chemist Dmitri Mendeleev (1834–1907) made an early attempt at finding some order among the chemical elements. He was trying to organize the elements for the table of contents of a book he was writing. He arranged the atoms in a table similar to that shown in Figure 42.19, according to their atomic masses and chemical similarities. The first table Mendeleev proposed contained many blank spaces, and he boldly stated that the gaps were there only because the elements had not yet been discovered. By noting the columns in which some missing elements should be located, he was able to make rough predictions about their chemical properties. Within 20 years of this announcement, most of these elements were indeed discovered.

The elements in the **periodic table** (Fig. 42.19) are arranged so that all those in a column have similar chemical properties. For example, consider the elements in the last column, which are all gases at room temperature: He (helium), Ne (neon), Ar (argon), Kr (krypton), Xe (xenon), and Rn (radon). The outstanding characteristic of all these elements is that they do not normally take part in chemical reactions; that is, they do not readily join with other atoms to form molecules. They are therefore called **inert gases** or **noble gases**.

![Periodic Table](image_url)

**Figure 42.19** The periodic table of the elements is an organized tabular representation of the elements that shows their periodic chemical behavior. Elements in a given column have similar chemical behavior. This table shows the chemical symbol for the element, the atomic number, and the electron configuration. A more complete periodic table is available in Appendix C.
We can partially understand this behavior by looking at the electronic configurations in Figure 42.19. The chemical behavior of an element depends on the outermost shell that contains electrons. The electronic configuration for helium is 1s², and the n = 1 shell (which is the outermost shell because it is the only shell) is filled. Also, the energy of the atom in this configuration is considerably lower than the energy for the configuration in which an electron is in the next available level, the 2s subshell. Next, look at the electronic configuration for neon, 1s²2s²2p⁶. Again, the outermost shell (n = 2 in this case) is filled and a wide gap in energy occurs between the filled 2p subshell and the next available one, the 3s subshell. Argon has the configuration 1s²2s²2p⁶3s²3p⁶. Here, it is only the 3p subshell that is filled, but again a wide gap in energy occurs between the filled 3p subshell and the next available one, the 3d subshell. This pattern continues through all the noble gases. Krypton has a filled 4p subshell, xenon a filled 5p subshell, and radon a filled 6p subshell.

The column to the left of the noble gases in the periodic table consists of a group of elements called the halogens: fluorine, chlorine, bromine, iodine, and astatine. At room temperature, fluorine and chlorine are gases, bromine is a liquid, and iodine and astatine are solids. In each of these atoms, the outer subshell is one electron short of being filled. As a result, the halogens are chemically very active, readily accepting an electron from another atom to form a closed shell. The halogens tend to form strong ionic bonds with atoms at the other side of the periodic table. (We shall discuss ionic bonds in Chapter 43.) In a halogen lightbulb, bromine or iodine atoms combine with tungsten atoms evaporated from the filament and return them to the filament, resulting in a longer-lasting lightbulb. In addition, the filament can be operated at a higher temperature than in ordinary lightbulbs, giving a brighter and whiter light.

At the left side of the periodic table, the Group I elements consist of hydrogen and the alkali metals: lithium, sodium, potassium, rubidium, cesium, and francium. Each of these atoms contains one electron in a subshell outside of a closed subshell. Therefore, these elements easily form positive ions because the lone electron is bound with a relatively low energy and is easily removed. Therefore, the alkali metal atoms are chemically active and form very strong bonds with halogen atoms. For example, table salt, NaCl, is a combination of an alkali metal and a halogen. Because the outer electron is weakly bound, pure alkali metals tend to be good electrical conductors. Because of their high chemical activity, however, they are not generally found in nature in pure form.

It is interesting to plot ionization energy versus atomic number Z as in Figure 42.20. Notice the pattern of ΔZ = 2, 8, 18, 18, 32 for the various peaks. This pattern follows from the exclusion principle and helps explain why the elements repeat their chemical properties in groups. For example, the peaks at Z = 2, 10, 18,
and 36 correspond to the noble gases helium, neon, argon, and krypton, respectively, which, as we have mentioned, all have filled outermost shells. These elements have relatively high ionization energies and similar chemical behavior.

### 42.8 More on Atomic Spectra: Visible and X-Ray

In Section 42.1, we discussed the observation and early interpretation of visible spectral lines from gases. These spectral lines have their origin in transitions between quantized atomic states. We shall investigate these transitions more deeply in these final three sections of this chapter.

A modified energy-level diagram for hydrogen is shown in Figure 42.21. In this diagram, the allowed values of \( \ell \) for each shell are separated horizontally. Figure 42.21 shows only those states up to \( n = 5 \); the shells from \( n = 4 \) upward would have more sets of states to the right, which are not shown. Transitions for which \( \ell \) does not change are very unlikely to occur and are called forbidden transitions. (Such transitions actually can occur, but their probability is very low relative to the probability of “allowed” transitions.) The various diagonal lines represent allowed transitions between stationary states. Whenever an atom makes a transition from a higher energy state to a lower one, a photon of light is emitted. The frequency of this photon is \( f = \frac{\Delta E}{h} \), where \( \Delta E \) is the energy difference between the two states and \( h \) is Planck’s constant. The selection rules for the allowed transitions are

\[
\Delta \ell = \pm 1 \quad \text{and} \quad \Delta m_\ell = 0, \pm 1
\]

Figure 42.21 shows that the orbital angular momentum of an atom changes when it makes a transition to a lower energy state. Therefore, the atom alone is a non-isolated system for angular momentum. If we consider the atom–photon system, however, it must be an isolated system for angular momentum because nothing else is interacting with this system. The photon involved in the process must carry angular momentum away from the atom when the transition occurs. In fact, the photon has an angular momentum equivalent to that of a particle having a spin of 1. We have now determined over several chapters that a photon has energy, linear momentum, and angular momentum, and each of these is conserved in atomic processes.

Recall from Equation 42.19 that the allowed energies for one-electron atoms and ions, such as hydrogen and He\(^+\), are

\[
E_n = -\frac{k e^2}{2\alpha_0} \left( \frac{Z^2}{n^2} \right) = -\left(\frac{13.6 \text{ eV}}{n^2}\right) \quad (42.35)
\]

This equation was developed from the Bohr theory, but it serves as a good first approximation in quantum theory as well. For multielectron atoms, the positive nuclear charge \( Z e \) is largely shielded by the negative charge of the inner-shell electrons. Therefore, the outer electrons interact with a net charge that is smaller than the nuclear charge. The expression for the allowed energies for multielectron atoms has the same form as Equation 42.35 with \( Z \) replaced by an effective atomic number \( Z_{\text{eff}} \):

\[
E_n = -\frac{\left(13.6 \text{ eV}\right)Z_{\text{eff}}^2}{n^2} \quad (42.36)
\]

where \( Z_{\text{eff}} \) depends on \( n \) and \( \ell \).

### X-Ray Spectra

X-rays are emitted when high-energy electrons or any other charged particles bombard a metal target. The x-ray spectrum typically consists of a broad continuous band containing a series of sharp lines as shown in Figure 42.22. In Section 34.6,
we mentioned that an accelerated electric charge emits electromagnetic radiation. The x-rays in Figure 42.22 are the result of the slowing down of high-energy electrons as they strike the target. It may take several interactions with the atoms of the target before the electron gives up all its kinetic energy. The amount of kinetic energy given up in any interaction can vary from zero up to the entire kinetic energy of the electron. Therefore, the wavelength of radiation from these interactions lies in a continuous range from some minimum value up to infinity. It is this general slowing down of the electrons that provides the continuous curve in Figure 42.22, which shows the cutoff of x-rays below a minimum wavelength value that depends on the kinetic energy of the incoming electrons. X-ray radiation with its origin in the slowing down of electrons is called bremsstrahlung, the German word for “braking radiation.”

Extremely high-energy bremsstrahlung can be used for the treatment of cancerous tissues. Figure 42.23 shows a machine that uses a linear accelerator to accelerate electrons up to 18 MeV and smash them into a tungsten target. The result is a beam of photons, up to a maximum energy of 18 MeV, which is actually in the gamma-ray range in Figure 34.13. This radiation is directed at the tumor in the patient.

The discrete lines in Figure 42.22, called characteristic x-rays and discovered in 1908, have a different origin. Their origin remained unexplained until the details of atomic structure were understood. The first step in the production of characteristic x-rays occurs when a bombarding electron collides with a target atom. The electron must have sufficient energy to remove an inner-shell electron from the atom. The vacancy created in the shell is filled when an electron in a higher level drops down into the level containing the vacancy. The existence of characteristic lines in an x-ray spectrum is further direct evidence of the quantization of energy in atomic systems.

The time interval for atomic transitions to happen is very short, less than $10^{-9}$ s. This transition is accompanied by the emission of a photon whose energy equals the difference in energy between the two levels. Typically, the energy of such transitions is greater than 1 000 eV and the emitted x-ray photons have wavelengths in the range of 0.01 nm to 1 nm.

Let’s assume the incoming electron has dislodged an atomic electron from the innermost shell, the K shell. If the vacancy is filled by an electron dropping from the next higher shell—the L shell—the photon emitted has an energy corresponding to the $K\alpha$ characteristic x-ray line on the curve of Figure 42.22. In this notation, K refers to the final level of the electron and the subscript $\alpha$, as the first letter of the Greek alphabet, refers to the initial level as the first one above the final level. Figure 42.24 shows this transition as well as others discussed below. If the vacancy in the K shell is filled by an electron dropping from the M shell, the $K\beta$ line in Figure 42.22 is produced.

Other characteristic x-ray lines are formed when electrons drop from upper levels to vacancies other than those in the K shell. For example, L lines are produced when vacancies in the L shell are filled by electrons dropping from higher shells. An $L\alpha$ line is produced as an electron drops from the M shell to the L shell, and an $L\beta$ line is produced by a transition from the N shell to the L shell.

Although multielectron atoms cannot be analyzed exactly with either the Bohr model or the Schrödinger equation, we can apply Gauss’s law from Chapter 24 to make some surprisingly accurate estimates of expected x-ray energies and wavelengths. Consider an atom of atomic number Z in which one of the two electrons in the K shell has been ejected. Imagine drawing a gaussian sphere immediately inside the most probable radius of the L electrons. The electric field at the position of the L electrons is a combination of the fields created by the nucleus, the single K electron, the other L electrons, and the outer electrons. The wave functions of the outer electrons are such that the electrons have a very high probability of being farther from the nucleus than the L electrons are. Therefore, the outer
electrons are much more likely to be outside the gaussian surface than inside and, on average, do not contribute significantly to the electric field at the position of the L electrons. The effective charge inside the gaussian surface is the positive nuclear charge and one negative charge due to the single K electron. Ignoring the interactions between L electrons, a single L electron behaves as if it experiences an electric field due to a charge \((Z - 1)e\) enclosed by the gaussian surface. The nuclear charge is shielded by the electron in the K shell such that \(Z_{\text{eff}}\) in Equation 42.36 is \(Z - 1\). For higher-level shells, the nuclear charge is shielded by electrons in all the inner shells.

We can now use Equation 42.36 to estimate the energy associated with an electron in the L shell:

\[
E_L = -(Z - 1)^2 \frac{13.6 \text{ eV}}{2^2}
\]

After the atom makes the transition, there are two electrons in the K shell. We can approximate the energy associated with one of these electrons as that of a one-electron atom. (In reality, the nuclear charge is reduced somewhat by the negative charge of the other electron, but let’s ignore this effect.) Therefore,

\[
E_K \approx -Z^2(13.6 \text{ eV}) \tag{42.37}
\]

As Example 42.5 shows, the energy of the atom with an electron in an M shell can be estimated in a similar fashion. Taking the energy difference between the initial and final levels, we can then calculate the energy and wavelength of the emitted photon.

In 1914, Henry G. J. Moseley (1887–1915) plotted \(\frac{1}{\lambda}\) versus the \(Z\) values for a number of elements where \(\lambda\) is the wavelength of the \(K_a\) x-ray line of each element. He found that the plot is a straight line as in Figure 42.25, which is consistent with rough calculations of the energy levels given by Equation 42.37. From this plot, Moseley determined the \(Z\) values of elements that had not yet been discovered and produced a periodic table in excellent agreement with the known chemical properties of the elements. Until that experiment, atomic numbers had been merely placeholders for the elements that appeared in the periodic table, the elements being ordered according to mass.

**Quick Quiz 42.5** In an x-ray tube, as you increase the energy of the electrons striking the metal target, do the wavelengths of the characteristic x-rays (a) increase, (b) decrease, or (c) remain constant?

**Quick Quiz 42.6** True or False: It is possible for an x-ray spectrum to show the continuous spectrum of x-rays without the presence of the characteristic x-rays.

---

**Example 42.5 Estimating the Energy of an X-Ray**

Estimate the energy of the characteristic x-ray emitted from a tungsten target when an electron drops from an M shell \((n = 3\) state\) to a vacancy in the K shell \((n = 1\) state\). The atomic number for tungsten is \(Z = 74\).

**Solution**

**Conceptualize** Imagine an accelerated electron striking a tungsten atom and ejecting an electron from the K shell \((n = 1)\). Subsequently, an electron in the M shell \((n = 3)\) drops down to fill the vacancy and the energy difference between the states is emitted as an x-ray photon.

**Categorize** We estimate the results using equations developed in this section, so we categorize this example as a substitution problem.

Use Equation 42.37 and \(Z = 74\) for tungsten to estimate the energy associated with the electron in the K shell:

\[
E_K \approx -(74)^2(13.6 \text{ eV}) = -7.4 \times 10^4 \text{ eV}
\]
42.9 Spontaneous and Stimulated Transitions

We have seen that an atom absorbs and emits electromagnetic radiation only at frequencies that correspond to the energy differences between allowed states. Let’s now examine more details of these processes. Consider an atom having the allowed energy levels labeled \( E_1, E_2, E_3, \ldots \). When radiation is incident on the atom, only those photons whose energy \( hf \) matches the energy separation \( \Delta E \) between two energy levels can be absorbed by the atom as represented in Figure 42.26. This process is called **stimulated absorption** because the photon stimulates the atom to make the upward transition. At ordinary temperatures, most of the atoms in a sample are in the ground state. If a vessel containing many atoms of a gaseous element is illuminated with radiation of all possible photon frequencies (that is, a continuous spectrum), only those photons having energy \( E_2 - E_1 \), \( E_3 - E_1 \), \( E_4 - E_1 \), and so on are absorbed by the atoms. As a result of this absorption, some of the atoms are raised to excited states.

Once an atom is in an excited state, the excited atom can make a transition back to a lower energy level, emitting a photon in the process as in Figure 42.27. This process is known as **spontaneous emission** because it happens naturally, without requiring an event to trigger the transition. Typically, an atom remains in an excited state for only about \( 10^{-8} \) s.

In addition to spontaneous emission, **stimulated emission** occurs. Suppose an atom is in an excited state \( E_2 \) as in Figure 42.28 (page 1326). If the excited state is a metastable state—that is, if its lifetime is much longer than the typical \( 10^{-8} \) s lifetime of...
excited states—the time interval until spontaneous emission occurs is relatively long. Let’s imagine that during that interval a photon of energy $hf = E_2 - E_1$ is incident on the atom. One possibility is that the photon energy is sufficient for the photon to ionize the atom. Another possibility is that the interaction between the incoming photon and the atom causes the atom to return to the ground state and thereby emit a second photon with energy $hf = E_2 - E_1$. In this process, the incident photon is not absorbed; therefore, after the stimulated emission, two photons with identical energy exist: the incident photon and the emitted photon. The two are in phase and travel in the same direction, which is an important consideration in lasers, discussed next.

42.10 Lasers

In this section, we explore the nature of laser light and a variety of applications of lasers in our technological society. The primary properties of laser light that make it useful in these technological applications are the following:

- Laser light is coherent. The individual rays of light in a laser beam maintain a fixed phase relationship with one another.
- Laser light is monochromatic. Light in a laser beam has a very narrow range of wavelengths.
- Laser light has a small angle of divergence. The beam spreads out very little, even over large distances.

To understand the origin of these properties, let’s combine our knowledge of atomic energy levels from this chapter with some special requirements for the atoms that emit laser light.

We have described how an incident photon can cause atomic energy transitions either upward (stimulated absorption) or downward (stimulated emission). The two processes are equally probable. When light is incident on a collection of atoms, a net absorption of energy usually occurs because when the system is in thermal equilibrium, many more atoms are in the ground state than in excited states. If the situation can be inverted so that more atoms are in an excited state than in the ground state, however, a net emission of photons can result. Such a condition is called **population inversion**.

Population inversion is, in fact, the fundamental principle involved in the operation of a **laser** (an acronym for **light amplification by stimulated emission of radiation**).
The full name indicates one of the requirements for laser light: to achieve laser action, the process of stimulated emission must occur.

Suppose an atom is in the excited state $E_2$ as in Figure 42.28 and a photon with energy $hf = E_2 - E_1$ is incident on it. As described in Section 42.9, the incoming photon can stimulate the excited atom to return to the ground state and thereby emit a second photon having the same energy $hf$ and traveling in the same direction. The incident photon is not absorbed, so after the stimulated emission, there are two identical photons: the incident photon and the emitted photon. The emitted photon is in phase with the incident photon. These photons can stimulate other atoms to emit photons in a chain of similar processes. The many photons produced in this fashion are the source of the intense, coherent light in a laser.

For the stimulated emission to result in laser light, there must be a buildup of photons in the system. The following three conditions must be satisfied to achieve this buildup:

- The system must be in a state of population inversion: there must be more atoms in an excited state than in the ground state. That must be true because the number of photons emitted must be greater than the number absorbed.
- The excited state of the system must be a metastable state, meaning that its lifetime must be long compared with the usually short lifetimes of excited states, which are typically $10^{-8}$ s. In this case, the population inversion can be established and stimulated emission is likely to occur before spontaneous emission.
- The emitted photons must be confined in the system long enough to enable them to stimulate further emission from other excited atoms. That is achieved by using reflecting mirrors at the ends of the system. One end is made totally reflecting, and the other is partially reflecting. A fraction of the light intensity passes through the partially reflecting end, forming the beam of laser light (Fig. 42.29).

One device that exhibits stimulated emission of radiation is the helium–neon gas laser. Figure 42.30 is an energy-level diagram for the neon atom in this system. The mixture of helium and neon is confined to a glass tube that is sealed at the ends by mirrors. A voltage applied across the tube causes electrons to sweep through the tube, colliding with the atoms of the gases and raising them into excited states. Neon atoms are excited to state $E_3^*$ through this process (the asterisk indicates a metastable state) and also as a result of collisions with excited helium atoms. Stimulated emission occurs, causing neon atoms to make transitions to state $E_2$. Neighboring excited atoms are also stimulated. The result is the production of coherent light at a wavelength of 632.8 nm.
Chapter 42 Atomic Physics

Applications

Since the development of the first laser in 1960, tremendous growth has occurred in laser technology. Lasers that cover wavelengths in the infrared, visible, and ultraviolet regions are now available. Laser diodes are used as laser pointers, and in surveying and construction rangefinders, fiber optic communication, DVD and Blu-ray players, and bar code readers. Carbon dioxide lasers are used in industry for welding and cutting, such as the process shown to cut fabric in Figure 42.31. Excimer lasers are used in lasik eye surgery. A variety of other types of lasers exist and are used in various applications. These applications are possible because of the unique characteristics of laser light. In addition to being highly monochromatic, laser light is also highly directional and can be sharply focused to produce regions of extremely intense light energy (with energy densities $10^{12}$ times the density in the flame of a typical cutting torch).

Lasers are used in precision long-range distance measurement (range finding). In recent years, it has become important in astronomy and geophysics to measure as precisely as possible the distances from various points on the surface of the Earth to a point on the Moon’s surface. To facilitate these measurements, the Apollo astronauts set up a 0.5-m square of reflector prisms on the Moon, which enables laser pulses directed from an Earth-based station to be retroreflected to the same station (see Fig. 35.8a). Using the known speed of light and the measured round-trip travel time of a laser pulse, the Earth–Moon distance can be determined to a precision of better than 10 cm.

Because various laser wavelengths can be absorbed in specific biological tissues, lasers have a number of medical applications. For example, certain laser procedures have greatly reduced blindness in patients with glaucoma and diabetes. Glaucoma is a widespread eye condition characterized by a high fluid pressure in the eye, a condition that can lead to destruction of the optic nerve. A simple laser operation (iridectomy) can “burn” open a tiny hole in a clogged membrane, relieving the destructive pressure. A serious side effect of diabetes is neovascularization, the proliferation of weak blood vessels, which often leak blood. When neovascularization occurs in the retina, vision deteriorates (diabetic retinopathy) and finally is destroyed. Today, it is possible to direct the green light from an argon ion laser through the clear eye lens and eye fluid, focus on the retina edges, and photoaggregate the leaky vessels. Even people who have only minor vision defects such as nearsightedness are benefiting from the use of lasers to reshape the cornea, changing its focal length and reducing the need for eyeglasses.

Laser surgery is now an everyday occurrence at hospitals and medical clinics around the world. Infrared light at 10 μm from a carbon dioxide laser can cut through muscle tissue, primarily by vaporizing the water contained in cellular material. Laser power of approximately 100 W is required in this technique. The advantage of the “laser knife” over conventional methods is that laser radiation cuts tissue and coagulates blood at the same time, leading to a substantial reduction in blood loss. In addition, the technique virtually eliminates cell migration, an important consideration when tumors are being removed.
A laser beam can be trapped in fine optical fiber light guides (endoscopes) by means of total internal reflection. An endoscope can be introduced through natural orifices, conducted around internal organs, and directed to specific interior body locations, eliminating the need for invasive surgery. For example, bleeding in the gastrointestinal tract can be optically cauterized by endoscopes inserted through the patient’s mouth.

In biological and medical research, it is often important to isolate and collect unusual cells for study and growth. A laser cell separator exploits the tagging of specific cells with fluorescent dyes. All cells are then dropped from a tiny charged nozzle and laser-scanned for the dye tag. If triggered by the correct light-emitting tag, a small voltage applied to parallel plates deflects the falling electrically charged cell into a collection beaker.

An exciting area of research and technological applications arose in the 1990s with the development of laser trapping of atoms. One scheme, called optical molasses and developed by Steven Chu of Stanford University and his colleagues, involves focusing six laser beams onto a small region in which atoms are to be trapped. Each pair of lasers is along one of the x, y, and z axes and emits light in opposite directions (Fig. 42.32). The frequency of the laser light is tuned to be slightly below the absorption frequency of the subject atom. Imagine that an atom has been placed into the trap region and moves along the positive x axis toward the laser that is emitting light toward it (the rightmost laser on the x axis in Fig. 42.32). Because the atom is moving, the light from the laser appears Doppler-shifted upward in frequency in the reference frame of the atom. Therefore, a match between the Doppler-shifted laser frequency and the absorption frequency of the atom exists and the atom absorbs photons. The momentum carried by these photons results in the atom being pushed back to the center of the trap. By incorporating six lasers, the atoms are pushed back into the trap regardless of which way they move along any axis.

In 1986, Chu developed optical tweezers, a device that uses a single tightly focused laser beam to trap and manipulate small particles. In combination with microscopes, optical tweezers have opened up many new possibilities for biologists. Optical tweezers have been used to manipulate live bacteria without damage, move chromosomes within a cell nucleus, and measure the elastic properties of a single DNA molecule. Chu shared the 1997 Nobel Prize in Physics with two of his colleagues for the development of the techniques of optical trapping.

An extension of laser trapping, laser cooling, is possible because the normal high speeds of the atoms are reduced when they are restricted to the region of the trap. As a result, the temperature of the collection of atoms can be reduced to a few microkelvins. The technique of laser cooling allows scientists to study the behavior of atoms at extremely low temperatures (Fig. 42.33).

The wavelengths of spectral lines from hydrogen, called the Balmer series, can be described by the equation

\[ \frac{1}{\lambda} = R_H \left( \frac{1}{2^2} - \frac{1}{n^2} \right) \quad n = 3, 4, 5, \ldots \]

where \( R_H \) is the Rydberg constant. The spectral lines corresponding to values of \( n \) from 3 to 6 are in the visible range of the electromagnetic spectrum. Values of \( n \) higher than 6 correspond to spectral lines in the ultraviolet region of the spectrum.
The Bohr model of the atom is successful in describing some details of the spectra of atomic hydrogen and hydrogen-like ions. One basic assumption of the model is that the electron can exist only in discrete orbits such that the angular momentum of the electron is an integral multiple of $\hbar/2\pi = \hbar$. When we assume circular orbits and a simple Coulomb attraction between electron and proton, the energies of the quantum states for hydrogen are calculated to be

$$E_n = -\frac{k_e e^2}{2a_0}\left(\frac{1}{n^2}\right) n = 1, 2, 3, \ldots$$  \hspace{0.5cm} (42.13)

where $n$ is an integer called the quantum number, $k_e$ is the Coulomb constant, $e$ is the electronic charge, and $a_0 = 0.0529 \text{ nm}$ is the Bohr radius.

If the electron in a hydrogen atom makes a transition from an orbit whose quantum number is $n_i$ to one whose quantum number is $n_f$, where $n_f < n_i$, a photon is emitted by the atom. The frequency of this photon is

$$f = \frac{k_e e^2}{2a_0}\left(\frac{1}{n_i^2} - \frac{1}{n_f^2}\right)$$  \hspace{0.5cm} (42.15)

Quantum mechanics can be applied to the hydrogen atom by the use of the potential energy function $U(r) = -k_e e^2/r$ in the Schrödinger equation. The solution to this equation yields wave functions for allowed states and allowed energies:

$$E_n = -\frac{k_e e^2}{2a_0}\frac{1}{n^2} = -\frac{13.606 \text{ eV}}{n^2} n = 1, 2, 3, \ldots$$  \hspace{0.5cm} (42.21)

where $n$ is the principal quantum number. The allowed wave functions depend on three quantum numbers: $n$, $\ell$, and $m$, where $\ell$ is the orbital quantum number and $m$ is the orbital magnetic quantum number. The restrictions on the quantum numbers are

$$n = 1, 2, 3, \ldots$$
$$\ell = 0, 1, 2, \ldots, n - 1$$
$$m = -\ell, -\ell + 1, \ldots, \ell - 1, \ell$$

All states having the same principal quantum number $n$ form a shell, identified by the letters K, L, M, . . . (corresponding to $n = 1, 2, 3, \ldots$). All states having the same values of $n$ and $\ell$ form a subshell, designated by the letters $s, p, d, f, \ldots$ (corresponding to $\ell = 0, 1, 2, 3, \ldots$).

An atom in a state characterized by a specific value of $n$ can have the following values of $\ell$, the magnitude of the atom’s orbital angular momentum $L$:

$$L = \sqrt{\ell(\ell + 1)} \hbar$$
$$\ell = 0, 1, 2, \ldots, n - 1$$  \hspace{0.5cm} (42.27)

The allowed values of the projection of $\mathbf{L}$ along the $z$ axis are

$$L_z = m_\ell \hbar$$  \hspace{0.5cm} (42.28)

Only discrete values of $L_z$ are allowed as determined by the restrictions on $m$. This quantization of $L_z$ is referred to as space quantization.

The exclusion principle states that no two electrons in an atom can be in the same quantum state. In other words, no two electrons can have the same set of quantum numbers $n$, $\ell$, $m$, and $m$. Using this principle, the electronic configurations of the elements can be determined. This principle serves as a basis for understanding atomic structure and the chemical properties of the elements.

The electron has an intrinsic angular momentum called the spin angular momentum. Electron spin can be described by a single quantum number $s = \frac{1}{2}$. To describe a quantum state completely, it is necessary to include a fourth quantum number $m_s$, called the spin magnetic quantum number. This quantum number can have only two values, $\pm \frac{1}{2}$. The magnitude of the spin angular momentum is

$$S = \frac{\sqrt{3}}{2} \hbar$$  \hspace{0.5cm} (42.30)

and the $z$ component of $\mathbf{S}$ is

$$S_z = m_s \hbar = \pm \frac{1}{2} \hbar$$  \hspace{0.5cm} (42.31)

That is, the spin angular momentum is also quantized in space, as specified by the spin magnetic quantum number $m_s = \pm \frac{1}{2}$.

The magnetic moment $\mu_{\text{spin}}$ associated with the spin angular momentum of an electron is

$$\mu_{\text{spin}} = -\frac{\hbar}{m_e} \mathbf{S}$$  \hspace{0.5cm} (42.32)

The $z$ component of $\mu_{\text{spin}}$ can have the values

$$\mu_{\text{spin},z} = \pm \frac{\hbar}{2m_e}$$  \hspace{0.5cm} (42.33)
Objective Questions

1. (i) What is the principal quantum number of the initial state of an atom as it emits an $M_\ell$ line in an x-ray spectrum? (a) 1 (b) 2 (c) 3 (d) 4 (e) 5 (ii) What is the principal quantum number of the final state for this transition? Choose from the same possibilities as in part (i).

2. If an electron in an atom has the quantum numbers $n = 3$, $\ell = 2$, $m_\ell = 1$, and $m_s = \frac{1}{2}$, what state is it in? (a) 3s (b) 3p (c) 3d (d) 4d (e) 3f

3. An electron in the $n = 5$ energy level of hydrogen undergoes a transition to the $n = 3$ energy level. What is the wavelength of the photon the atom emits in this process? (a) $2.28 \times 10^{-6}$ m (b) $8.20 \times 10^{-7}$ m (c) $3.64 \times 10^{-7}$ m (d) $1.28 \times 10^{-6}$ m (e) $5.92 \times 10^{-6}$ m

4. Consider the $n = 3$ energy level in a hydrogen atom. How many electrons can be placed in this level? (a) 1 (b) 2 (c) 8 (d) 9 (e) 18

5. Which of the following is not one of the basic assumptions of the Bohr model of hydrogen? (a) Only certain electron orbits are stable and allowed. (b) The electron moves in circular orbits about the proton under the influence of the Coulomb force. (c) The charge on the electron is quantized. (d) Radiation is emitted by the atom when the electron moves from a higher energy state to a lower energy state. (e) The angular momentum associated with the electron’s orbital motion is quantized.

6. Let $-E$ represent the energy of a hydrogen atom. (i) What is the kinetic energy of the electron? (a) $2E$ (b) $E$ (c) 0 (d) $-E$ (e) $-2E$ (ii) What is the potential energy of the atom? Choose from the same possibilities (a) through (e).

7. The periodic table is based on which of the following principles? (a) The uncertainty principle. (b) All electrons in an atom must have the same set of quantum numbers. (c) Energy is conserved in all interactions. (d) All electrons in an atom are in orbitals having the same energy. (e) No two electrons in an atom can have the same set of quantum numbers.

8. (a) Can a hydrogen atom in the ground state absorb a photon of energy less than 13.6 eV? (b) Can this atom absorb a photon of energy greater than 13.6 eV?

9. Which of the following electronic configurations are not allowed for an atom? Choose all correct answers. (a) $2s^22p^6$ (b) $3s^23p^2$ (c) $3d^74s^2$ (d) $3d^{10}4s^24p^6$ (e) $1s^22s^22p^6$

10. What can be concluded about a hydrogen atom with its electron in the $d$ state? (a) The atom is ionized. (b) The orbital quantum number is $\ell = 1$. (c) The principal quantum number is $n = 2$. (d) The atom is in its ground state. (e) The orbital angular momentum of the atom is not zero.

11. (i) Rank the following transitions for a hydrogen atom from the transition with the greatest gain in energy to that with the greatest loss, showing any cases of equal- ity. (a) $n_1 = 2; n_f = 5$ (b) $n_1 = 5; n_f = 3$ (c) $n_1 = 7; n_f = 4$ (d) $n_1 = 4; n_f = 7$ (ii) Rank the same transitions as in part (i) according to the wavelength of the photon absorbed or emitted by an otherwise isolated atom from greatest wavelength to smallest.

12. When an atom emits a photon, what happens? (a) One of its electrons leaves the atom. (b) The atom moves to a state of higher energy. (c) The atom moves to a state of lower energy. (d) One of its electrons collides with another particle. (e) None of those events occur.

13. (a) In the hydrogen atom, can the quantum number $n$ increase without limit? (b) Can the frequency of possible discrete lines in the spectrum of hydrogen increase without limit? (c) Can the wavelength of possible discrete lines in the spectrum of hydrogen increase without limit?

14. Consider the quantum numbers (a) $n$, (b) $\ell$, (c) $m_\ell$, and (d) $m_s$. (i) Which of these quantum numbers are fractional as opposed to being integers? (ii) Which can sometimes attain negative values? (iii) Which can be zero?

15. When an electron collides with an atom, it can transfer all or some of its energy to the atom. A hydrogen atom is in its ground state. Incident on the atom are several electrons, each having a kinetic energy of 10.5 eV. What is the result? (a) The atom can be excited to a higher allowed state. (b) The atom is ionized. (c) The electrons pass by the atom without interaction.

---

**Objective Questions**

The x-ray spectrum of a metal target consists of a set of sharp characteristic lines superimposed on a broad continuous spectrum. **Bremsstrahlung** is x-radiation with its origin in the slowing down of high-energy electrons as they encounter the target. **Characteristic x-rays** are emitted by atoms when an electron undergoes a transition from an outer shell to a vacancy in an inner shell.

Atomic transitions can be described with three processes: **stimulated absorption**, in which an incoming photon raises the atom to a higher energy state; **spontaneous emission**, in which the atom makes a transition to a lower energy state, emitting a photon; and **stimulated emission**, in which an incident photon causes an excited atom to make a downward transition, emitting a photon identical to the incident one.
1. Why is stimulated emission so important in the operation of a laser?
2. An energy of about 21 eV is required to excite an electron in a helium atom from the 1s state to the 2s state. The same transition for the He⁺ ion requires approximately twice as much energy. Explain.
3. Why are three quantum numbers needed to describe the state of a one-electron atom (ignoring spin)?
4. Compare the Bohr theory and the Schrödinger treatment of the hydrogen atom, specifically commenting on their treatment of total energy and orbital angular momentum of the atom.
5. Could the Stern–Gerlach experiment be performed with ions rather than neutral atoms? Explain.
6. Why is a nonuniform magnetic field used in the Stern–Gerlach experiment?
7. Discuss some consequences of the exclusion principle.

8. (a) According to Bohr’s model of the hydrogen atom, what is the uncertainty in the radial coordinate of the electron? (b) What is the uncertainty in the radial component of the velocity of the electron? (c) In what way does the model violate the uncertainty principle?
9. Why do lithium, potassium, and sodium exhibit similar chemical properties?
10. It is easy to understand how two electrons (one spin up, one spin down) fill the n = 1 or K shell for a helium atom. How is it possible that eight more electrons are allowed in the n = 2 shell, filling the K and L shells for a neon atom?
11. Suppose the electron in the hydrogen atom obeyed classical mechanics rather than quantum mechanics. Why should a gas of such hypothetical atoms emit a continuous spectrum rather than the observed line spectrum?
12. Does the intensity of light from a laser fall off as 1/r²?

Section 42.1 Atomic Spectra of Gases

1. The wavelengths of the Lyman series for hydrogen are given by
   \[ \frac{1}{\lambda} = R \left( 1 - \frac{1}{n^2} \right) \quad n = 2, 3, 4, \ldots \]
   (a) Calculate the wavelengths of the first three lines in this series. (b) Identify the region of the electromagnetic spectrum in which these lines appear.

2. The wavelengths of the Paschen series for hydrogen are given by
   \[ \frac{1}{\lambda} = R \left( \frac{1}{3^2} - \frac{1}{n^2} \right) \quad n = 4, 5, 6, \ldots \]
   (a) Calculate the wavelengths of the first three lines in this series. (b) Identify the region of the electromagnetic spectrum in which these lines appear.

3. An isolated atom of a certain element emits light of wavelength 520 nm when the atom falls from its fifth excited state into its second excited state. The atom emits a photon of wavelength 410 nm when it drops from its sixth excited state into its second excited state. Find the wavelength of the light radiated when the atom makes a transition from its sixth to its fifth excited state.

4. An isolated atom of a certain element emits light of wavelength \( \lambda_{n1} \) when the atom falls from its state with quantum number m into its ground state of quantum number 1. The atom emits a photon of wavelength \( \lambda_{n2} \) when the atom falls from its state with quantum number n into its ground state. (a) Find the wavelength of the light radiated when the atom makes a transition from the m state to the n state. (b) Show that \( k_{n1} = |k_{n1} - k_{n2}| \), where \( k_i = 2\pi/\lambda_i \) is the wave number of the photon. This problem exemplifies the Ritz combination principle, an empirical rule formulated in 1908.

5. (a) What value of \( n_i \) is associated with the 94.96-nm spectral line in the Lyman series of hydrogen? (b) What If? Could this wavelength be associated with the Paschen series? (c) Could this wavelength be associated with the Balmer series?

Section 42.2 Early Models of the Atom

6. According to classical physics, a charge \( \epsilon \) moving with an acceleration \( a \) radiates energy at a rate
   \[ \frac{dE}{dt} = -\frac{1}{6\pi\epsilon_0} \frac{\epsilon^2 a^2}{c^3} \]
   (a) Show that an electron in a classical hydrogen atom (see Fig. 42.5) spirals into the nucleus at a rate
7. Review. In the Rutherford scattering experiment, 4.00-MeV alpha particles scatter off gold nuclei (containing 79 protons and 118 neutrons). Assume a particular alpha particle moves directly toward the gold nucleus and scatters backward at 180°, and that the gold nucleus remains fixed throughout the entire process. Determine (a) the distance of closest approach of the alpha particle to the gold nucleus and (b) the maximum force exerted on the alpha particle.

Section 42.3 Bohr’s Model of the Hydrogen Atom

Note: In this section, unless otherwise indicated, assume the hydrogen atom is treated with the Bohr model.

8. Show that the speed of the electron in the \(n\)th Bohr orbit in hydrogen is given by

\[
v_n = \frac{k_e e^2}{nh}
\]

9. How much energy is required to ionize hydrogen (a) when it is in the ground state and (b) when it is in the state for which \(n = 3\)?

10. What is the energy of a photon that, when absorbed by a hydrogen atom, could cause an electronic transition from (a) the \(n = 2\) state to the \(n = 5\) state and (b) the \(n = 4\) state to the \(n = 6\) state?

11. A photon is emitted when a hydrogen atom undergoes a transition from the \(n = 5\) state to the \(n = 3\) state. Calculate (a) the energy (in electron volts), (b) the wavelength, and (c) the frequency of the emitted photon.

12. The Balmer series for the hydrogen atom corresponds to electronic transitions that terminate in the state with quantum number \(n = 2\) as shown in Figure P42.12. Consider the photon of longest wavelength corresponding to a transition shown in the figure. Determine (a) its energy and (b) its wavelength. Consider the spectral line of shortest wavelength corresponding to a transition shown in the figure. Find (c) its photon energy and (d) its wavelength. (e) What is the shortest possible wavelength in the Balmer series?

![Figure P42.12](image)

13. For a hydrogen atom in its ground state, compute (a) the orbital speed of the electron, (b) the kinetic energy of the electron, and (c) the electric potential energy of the atom.

14. Two hydrogen atoms collide head-on and end up with zero kinetic energy. Each atom then emits light with a wavelength of 121.6 nm \((n = 2 \rightarrow n = 1\) transition). At what speed were the atoms moving before the collision?

15. (a) Calculate the angular momentum of the Moon due to its orbital motion about the Earth. In your calculation, use \(3.84 \times 10^8 \text{ m}\) as the average Earth–Moon distance and \(2.36 \times 10^5 \text{ s}\) as the period of the Moon in its orbit. (b) Assume that the Moon's angular momentum is described by Bohr's assumption \(\mathbf{p} = n \mathbf{h}\). Determine the corresponding quantum number. (c) By what fraction would the Earth–Moon distance have to be increased to raise the quantum number by 1?

16. A monochromatic beam of light is absorbed by a collection of ground-state hydrogen atoms in such a way that six different wavelengths are observed when the hydrogen relaxes back to the ground state. (a) What is the wavelength of the incident beam? Explain the steps in your solution. (b) What is the longest wavelength in the emission spectrum of these atoms? (c) To what portion of the electromagnetic spectrum and (d) to what series does it belong? (e) What is the shortest wavelength? (f) To what portion of the electromagnetic spectrum and (g) to what series does it belong?

17. A hydrogen atom is in its second excited state, corresponding to \(n = 3\). Find (a) the radius of the electron's Bohr orbit and (b) the de Broglie wavelength of the electron in this orbit.

18. A hydrogen atom is in its first excited state \((n = 2)\). Calculate (a) the radius of the orbit, (b) the linear momentum of the electron, (c) the angular momentum of the electron, (d) the kinetic energy of the electron, (e) the potential energy of the system, and (f) the total energy of the system.

19. A photon with energy 2.28 eV is absorbed by a hydrogen atom. Find (a) the minimum \(n\) for a hydrogen atom that can be ionized by such a photon and (b) the speed of the electron released from the state in part (a) when it is far from the nucleus.

20. An electron is in the \(n\)th Bohr orbit of the hydrogen atom. (a) Show that the period of the electron is \(T = n^3 t_0\) and determine the numerical value of \(t_0\). (b) On average, an electron remains in the \(n = 2\) orbit for approximately 10 \(\mu\)s before it jumps down to the \(n = 1\) (ground-state) orbit. How many revolutions does the electron make in the excited state? (c) Define the period of one revolution as an electron year, analogous to an Earth year being the period of the Earth's motion around the Sun. Explain whether we should think of the electron in the \(n = 2\) orbit as “living for a long time.”

21. (a) Construct an energy-level diagram for the \(\text{He}^+\) ion, for which \(Z = 2\), using the Bohr model. (b) What is the ionization energy for \(\text{He}^+\)?

Section 42.4 The Quantum Model of the Hydrogen Atom

22. A general expression for the energy levels of one-electron atoms and ions is

\[
E_n = -\frac{\mu k^2 q^2 z^2}{2h^2n^2}
\]

Problems
Here $\mu$ is the reduced mass of the atom, given by $\mu = m_1 m_2 / (m_1 + m_2)$, where $m_1$ is the mass of the electron and $m_2$ is the mass of the nucleus; $k$ is the Coulomb constant; and $q_1$ and $q_2$ are the charges of the electron and the nucleus, respectively. The wavelength for the $n = 3$ to $n = 2$ transition of the hydrogen atom is 656.3 nm (visible red light). What are the wavelengths for this same transition in (a) positronium, which consists of an electron and a positron, and (b) singly ionized helium? Note: A positron is a positively charged electron.

23. Atoms of the same element but with different numbers of neutrons in the nucleus are called isotopes. Ordinary hydrogen gas is a mixture of two isotopes containing either one- or two-particle nuclei. These isotopes are hydrogen-1, with a proton nucleus, and hydrogen-2, called deuterium, with a deuterium nucleus. A deuteron is one proton and one neutron bound together. Hydrogen-1 and deuterium have identical chemical properties, but they can be separated via an ultracentrifuge or by other methods. Their emission spectra show lines of the same colors at very slightly different wavelengths. (a) Use the equation given in Problem 22 to show that the difference in wavelength between the hydrogen-1 and deuteron spectral lines associated with a particular electron transition is given by

$$\lambda_1 - \lambda_0 = \left(1 - \frac{\mu_1}{\mu_0}\right)\lambda_1$$

(b) Find the wavelength difference for the Balmer alpha line of hydrogen, with wavelength 656.3 nm, emitted by an atom making a transition from an $n = 3$ state to an $n = 2$ state. Harold Urey observed this wavelength difference in 1931 and confirmed his discovery of deuterium.

24. An electron of momentum $p$ is at a distance $r$ from a stationary proton. The electron has kinetic energy $K = p^2 / 2m_e$. The atom has potential energy $U = -ke^2 / r$ and total energy $E = K + U$. If the electron is bound to the proton to form a hydrogen atom, its average position is at the proton but the uncertainty in its position is approximately equal to the radius $r$ of its orbit. The electron’s average vector momentum is zero, but its average squared momentum is approximately equal to the squared uncertainty in its momentum as given by the uncertainty principle. Treating the atom as a one-dimensional system, (a) estimate the uncertainty in the electron’s momentum in terms of $r$. Estimate the electron’s (b) kinetic energy and (c) total energy in terms of $r$. The actual value of $r$ is the one that minimizes the total energy, resulting in a stable atom. Find (d) that value of $r$ and (e) the resulting total energy. (f) State how your answers compare with the predictions of the Bohr theory.

Section 42.6 Physical Interpretation of the Quantum Numbers

26. For a spherically symmetric state of a hydrogen atom, the Schrödinger equation in spherical coordinates is

$$-\frac{\hbar^2}{2m_e} \left( \frac{d^2\psi}{dr^2} + \frac{2}{r} \frac{d\psi}{dr} \right) - \frac{ke^2}{r} \psi = E\psi$$

(a) Show that the 1s wave function for an electron in hydrogen,

$$\psi_{1s}(r) = \frac{1}{\sqrt{\pi a_0}} e^{-r/a_0}$$

satisfies the Schrödinger equation. (b) What is the energy of the atom for this state?

27. The radial function $R(r)$ of the wave function for a hydrogen atom in the $2p$ state is

$$\psi_{2p} = \frac{1}{\sqrt{5(2a_0)^{3/2}}} \frac{r}{a_0} e^{-r/2a_0}$$

What is the most likely distance from the nucleus to find an electron in the $2p$ state?

28. The ground-state wave function for the electron in a hydrogen atom is

$$\psi_{1s}(r) = \frac{1}{\sqrt{\pi a_0}} e^{-r/a_0}$$

where $r$ is the radial coordinate of the electron and $a_0$ is the Bohr radius. (a) Show that the wave function as given is normalized. (b) Find the probability of locating the electron between $r_1 = a_0/2$ and $r_2 = 3a_0/2$.

29. In an experiment, a large number of electrons are fired at a sample of neutral hydrogen atoms and observations are made of how the incident particles scatter. The electron in the ground state of a hydrogen atom is found to be momentarily at a distance $a_0/2$ from the nucleus in 1,000 of the observations. In this set of trials, how many times is the atomic electron observed at a distance $2a_0$ from the nucleus?

Section 42.5 The Wave Functions for Hydrogen

25. Plot the wave function $\psi_1(r)$ versus $r$ (see Eq. 42.22) and the radial probability density function $P_2(r)$ versus $r$ (see Eq. 42.25) for hydrogen. Let $r$ range from 0 to $1.5a_0$, where $a_0$ is the Bohr radius.

26. For a spherically symmetric state of a hydrogen atom, the Schrödinger equation in spherical coordinates is

$$-\frac{\hbar^2}{2m_e} \left( \frac{d^2\psi}{dr^2} + \frac{2}{r} \frac{d\psi}{dr} \right) - \frac{ke^2}{r} \psi = E\psi$$

(a) Show that the 1s wave function for an electron in hydrogen,

$$\psi_{1s}(r) = \frac{1}{\sqrt{\pi a_0}} e^{-r/a_0}$$

satisfies the Schrödinger equation. (b) What is the energy of the atom for this state?

27. The radial function $R(r)$ of the wave function for a hydrogen atom in the $2p$ state is

$$\psi_{2p} = \frac{1}{\sqrt{5(2a_0)^{3/2}}} \frac{r}{a_0} e^{-r/2a_0}$$

What is the most likely distance from the nucleus to find an electron in the $2p$ state?

28. The ground-state wave function for the electron in a hydrogen atom is

$$\psi_{1s}(r) = \frac{1}{\sqrt{\pi a_0}} e^{-r/a_0}$$

where $r$ is the radial coordinate of the electron and $a_0$ is the Bohr radius. (a) Show that the wave function as given is normalized. (b) Find the probability of locating the electron between $r_1 = a_0/2$ and $r_2 = 3a_0/2$.

29. In an experiment, a large number of electrons are fired at a sample of neutral hydrogen atoms and observations are made of how the incident particles scatter. The electron in the ground state of a hydrogen atom is found to be momentarily at a distance $a_0/2$ from the nucleus in 1,000 of the observations. In this set of trials, how many times is the atomic electron observed at a distance $2a_0$ from the nucleus?

Section 42.6 Physical Interpretation of the Quantum Numbers

30. List the possible sets of quantum numbers for the hydrogen atom associated with (a) the 3d subshell and (b) the 3p subshell.

31. If a hydrogen atom has orbital angular momentum $4.714 \times 10^{-34} \text{ J} \cdot \text{s}$, what is the orbital quantum number for the state of the atom?

32. Find all possible values of (a) $L_z$, (b) $L_z$, and (c) $\theta$ for a hydrogen atom in a 3d state.

33. Calculate the magnitude of the orbital angular momentum for a hydrogen atom in (a) the 4d state and (b) the 6f state.

34. How many sets of quantum numbers are possible for a hydrogen atom for which (a) $n = 1$, (b) $n = 2$, (c) $n = 3$, (d) $n = 4$, and (e) $n = 5$?

35. An electron in a sodium atom is in the N shell. Determine the maximum value the $z$ component of its angular momentum could have.

36. (a) Find the mass density of a proton, modeling it as a solid sphere of radius $1.00 \times 10^{-15} \text{ m}$. (b) What If? Consider a classical model of an electron as a uniform
solid sphere with the same density as the proton. Find its radius. (c) Imagine that this electron possesses spin angular momentum \( l_0 = \hbar / 2 \) because of classical rotation about the \( z \) axis. Determine the speed of a point on the equator of the electron. (d) State how this speed compares with the speed of light.

37. A hydrogen atom is in its fifth excited state, with principal quantum number 6. The atom emits a photon with a wavelength of 1 090 nm. Determine the maximum possible magnitude of the orbital angular momentum of the atom after emission.

38. Why is the following situation impossible? A photon of wavelength 88.0 nm strikes a clean aluminum surface, ejecting a photoelectron. The photoelectron then strikes a hydrogen atom in its ground state, transferring energy to it and exciting the atom to a higher quantum state.

39. The \( p^- \) meson has a charge of \(-e\), a spin quantum number of 1, and a mass 1 507 times that of the electron. The possible values for its spin magnetic quantum number are \(-1, 0, 1\). What If? Imagine that the electrons in atoms are replaced by \( p^- \) mesons. List the possible sets of quantum numbers for \( p^- \) mesons in the 3\( d \) subshell.

Section 42.7 The Exclusion Principle and the Periodic Table

40. (a) As we go down the periodic table, which subshell is filled first, the 3\( d \) or the 4\( s \) subshell? (b) Which electronic configuration has a lower energy, \([\text{Ar}]3d^44s^2\) or \([\text{Ar}]3d^54s^1?\) Note: The notation \([\text{Ar}]\) represents the filled configuration for argon. Suggestion: Which has the greater number of unpaired spins? (c) Identify the element with the electronic configuration in part (b).

41. (a) Write out the electronic configuration of the ground state for nitrogen (\( Z = 7 \)). (b) Write out the values for the possible set of quantum numbers \( n, \ell, m_s, \) and \( m \) for the electrons in nitrogen.

42. Devise a table similar to that shown in Figure 42.18 for atoms containing 11 through 19 electrons. Use Hund’s rule and educated guesswork.

43. A certain element has its outermost electron in a 3\( p \) subshell. It has valence +3 because it has three more electrons than a certain noble gas. What element is it?

44. Scanning through Figure 42.19 in order of increasing atomic number, notice that the electrons usually fill the subshells in such a way that those subshells with the lowest values of \( n + \ell \) are filled first. If two subshells have the same value of \( n + \ell \), the one with the lower value of \( n \) is generally filled first. Using these two rules, write the order in which the subshells are filled through \( n + \ell = 7 \).

45. Two electrons in the same atom both have \( n = 3 \) and \( \ell = 1 \). Assume the electrons are distinguishable, so that interchanging them defines a new state. (a) How many states of the atom are possible considering the quantum numbers these two electrons can have? (b) What If? How many states would be possible if the exclusion principle were inoperative?

46. For a neutral atom of element 110, what would be the probable ground-state electronic configuration?

47. Review. For an electron with magnetic moment \( \vec{\mu} \), in a magnetic field \( \mathbf{B} \), Section 29.5 showed the following. The electron–field system can be in a higher energy state with the \( z \) component of the electron's magnetic moment opposite the field or a lower energy state with the \( z \) component of the magnetic moment in the direction of the field. The difference in energy between the two states is \( 2\mu_B B \).

Under high resolution, many spectral lines are observed to be doublets. The most famous doublet is the pair of two yellow lines in the spectrum of sodium (the D lines), with wavelengths of 588.995 nm and 589.592 nm. Their existence was explained in 1925 by Goudsmit and Uhlenbeck, who postulated that an electron has intrinsic spin angular momentum. When the sodium atom is excited with its outermost electron in a 3\( p \) state, the orbital motion of the outermost electron creates a magnetic field. The atom’s energy is somewhat different depending on whether the electron is itself spin-up or spin-down in this field. Then the photon energy the atom radiates as it falls back into its ground state depends on the energy of the excited state. Calculate the magnitude of the internal magnetic field, mediating this so-called spin-orbit coupling.

Section 42.8 More on Atomic Spectra: Visible and X-Ray

48. In x-ray production, electrons are accelerated through a high voltage \( \Delta V \) and then decelerated by striking a target. Show that the shortest wavelength of an x-ray that can be produced is

\[
\lambda_{\text{min}} = \frac{1.24 \text{ nm} \cdot \text{eV}}{\Delta V}
\]

49. What minimum accelerating voltage would be required to produce an x-ray with a wavelength of 70.0 pm?

50. A tungsten target is struck by electrons that have been accelerated from rest through a 40.0-keV potential difference. Find the shortest wavelength of the radiation emitted.

51. A bismuth target is struck by electrons, and x-rays are emitted. Estimate (a) the M- to L-shell transitional energy for bismuth and (b) the wavelength of the x-ray emitted when an electron falls from the M shell to the L shell.

52. The 3\( p \) level of sodium has an energy of \(-3.0 \) eV, and the 3\( d \) level has an energy of \(-1.5 \) eV. (a) Determine \( Z_{\text{eff}} \) for each of these states. (b) Explain the difference.

53. (a) Determine the possible values of the quantum numbers \( \ell \) and \( m \) for the He\(^+ \) ion in the state corresponding to \( n = 3 \). (b) What is the energy of this state?

54. The K series of the discrete spectrum of tungsten contains wavelengths of 0.018 5 nm, 0.020 9 nm, and 0.021 5 nm. The K-shell ionization energy is 69.5 keV. Determine the ionization energies of the L, M, and N shells.

55. Use the method illustrated in Example 42.5 to calculate the wavelength of the x-ray emitted from a
molybdenum target \((Z = 42)\) when an electron moves from the L shell \((n = 2)\) to the K shell \((n = 1)\).

**56.** In x-ray production, electrons are accelerated through a high voltage and then decelerated by striking a target. (a) To make possible the production of x-rays of wavelength \(\lambda\), what is the minimum potential difference \(\Delta V\) through which the electrons must be accelerated? (b) State in words how the required potential difference depends on the wavelength. (c) Explain whether your result predicts the correct minimum wavelength in Figure 42.22. (d) Does the relationship from part (a) apply to other kinds of electromagnetic radiation besides x-rays? (e) What does the potential difference approach as \(\lambda\) goes to zero? (f) What does the potential difference approach as \(\lambda\) increases without limit?

**57.** When an electron drops from the M shell \((n = 3)\) to a vacancy in the K shell \((n = 1)\), the measured wavelength of the emitted x-ray is found to be 0.101 nm. Identify the element.

**Section 42.9 Spontaneous and Stimulated Transitions**

**Section 42.10 Lasers**

**58.** Figure P42.58 shows portions of the energy-level diagrams of the helium and neon atoms. An electrical discharge excites the He atom from its ground state (arbitrarily assigned the energy \(E_1 = 0\)) to its excited state of 20.61 eV. The excited He atom collides with a Ne atom in its ground state and excites this atom to the state at 20.66 eV. Lasing action takes place for electron transitions from \(E_2^*\) to \(E_1\) in the Ne atoms. From the data in the figure, show that the wavelength of the red He–Ne laser light is approximately 633 nm.

**59.** The carbon dioxide laser is one of the most powerful developed. The energy difference between the two laser levels is 0.117 eV. Determine (a) the frequency and (b) the wavelength of the radiation emitted by this laser. (c) In what portion of the electromagnetic spectrum is this radiation?

**60. Review.** A helium–neon laser can produce a green laser beam instead of a red one. Figure P42.60 shows the transitions involved to form the red beam and the green beam. After a population inversion is established, neon atoms make a variety of downward transitions in falling from the state labeled \(E_4^*\) down eventually to level \(E_1\) (arbitrarily assigned the energy \(E_1 = 0\)). The atoms emit both red light with a wavelength of 632.8 nm in a transition \(E_4^* - E_3\) and green light with a wavelength of 543 nm in a competing transition \(E_4^* - E_2\). (a) What is the energy \(E_4^*\)? Assume the atoms are in a cavity between mirrors designed to reflect the green light with high efficiency but to allow the red light to leave the cavity immediately. Then stimulated emission can lead to the buildup of a collimated beam of green light between the mirrors having a greater intensity than that of the red light. To constitute the radiated laser beam, a small fraction of the green light is permitted to escape by transmission through one mirror. The mirrors forming the resonant cavity can be made of layers of silicon dioxide (index of refraction \(n = 1.458\)) and titanium dioxide (index of refraction varies between 1.9 and 2.6). (b) How thick a layer of silicon dioxide, between layers of titanium dioxide, would minimize reflection of the red light? (c) What should be the thickness of a similar but separate layer of silicon dioxide to maximize reflection of the green light?

**61.** A ruby laser delivers a 10.0-ns pulse of 1.00-MW average power. If the photons have a wavelength of 694.3 nm, how many are contained in the pulse?

**62.** The number \(N\) of atoms in a particular state is called the population of that state. This number depends on the energy of that state and the temperature. In thermal equilibrium, the population of atoms in a state of energy \(E_n\) is given by a Boltzmann distribution expression

\[ N_n = N_0 e^{-\left(E_n - E_0\right)/k_B T} \]

where \(N_0\) is the population of the ground state of energy \(E_0\), \(k_B\) is Boltzmann's constant, and \(T\) is the absolute temperature. For simplicity, assume each energy level has only one quantum state associated with it. (a) Before the power is switched on, the neon atoms in a laser are in thermal equilibrium at 27.0°C. Find the equilibrium ratio of the populations of the states \(E_4^*\) and \(E_3\) shown for the red transition in Figure P42.60. Lasers operate by a clever artificial production of a “population inversion” between the upper and lower atomic energy states involved in the lasing transition. This term means that more atoms are in the upper excited state than in the lower one. Consider the \(E_4^* - E_3\) transition in Figure P42.60. Assume 2% more atoms occur in the upper state than in the lower. (b) To demonstrate how unnatural such a situation is, find the temperature for which the Boltzmann distribution describes a 2.00% population inversion. (c) Why does such a situation not occur naturally?
63. A neodymium–yttrium–aluminum garnet laser used in eye surgery emits a 3.00-mJ pulse in 1.00 ns, focused to a spot 30.0 μm in diameter on the retina. (a) Find (in SI units) the power per unit area at the retina. (In the optics industry, this quantity is called the irradiance.) (b) What energy is delivered by the pulse to an area of molecular size, taken as a circular area 0.600 nm in diameter?

64. Review. Figure 42.29 represents the light bouncing between two mirrors in a laser cavity as two traveling waves. These traveling waves moving in opposite directions constitute a standing wave. If the reflecting surfaces are metallic films, the electric field has nodes at both ends. The electromagnetic standing wave is analogous to the standing string wave represented in Figure 18.10. (a) Assume that a helium–neon laser has precisely flat and parallel mirrors 35.124 103 cm apart. Assume that the active medium can efficiently amplify only light with wavelengths between 632.8 40 nm and 632.8 80 nm. Find the number of components that constitute the laser light, and the wavelength of each component, precise to eight digits. (b) Find the root-mean-square speed for a neon atom at 120°C. (c) Show that at this temperature the Doppler effect for light emission by moving neon atoms should realistically make the bandwidth of the light amplifier larger than the 0.001 40 nm assumed in part (a).

Additional Problems

65. How much energy is required to ionize a hydrogen atom when it is in (a) the n = 2 state and (b) the n = 10 state?

66. The force on a magnetic moment \( \mu \) in a nonuniform magnetic field \( B_z \) is given by \( F_z = \mu_z (dB_z/dz) \). If a beam of silver atoms travels a horizontal distance of 1.00 m through such a field and each atom has a speed of 100 m/s, how strong must be the field gradient \( dB_z/dz \) to deflect the beam 1.00 mm?

67. Suppose a hydrogen atom is in the 2s state, with its wave function given by Equation 42.26. Taking \( r = a_0 \), calculate values for (a) \( \psi_2(a_0) \), (b) \( |\psi_2(a_0)|^2 \), and (c) \( P_2(a_0) \).

68. Review. (a) How much energy is required to cause an electron in hydrogen to move from the n = 1 state to the n = 2 state? (b) Suppose the atom gains this energy through collisions among hydrogen atoms at a high temperature. At what temperature would the average atomic kinetic energy \( \frac{1}{2} k_B T \) be great enough to excite the electron? Here \( k_B \) is Boltzmann’s constant.

69. In the technique known as electron spin resonance (ESR), a sample containing unpaired electrons is placed in a magnetic field. Consider a situation in which a single electron (not contained in an atom) is immersed in a magnetic field. In this simple situation, only two energy states are possible, corresponding to \( m_s = \pm \frac{1}{2} \). In ESR, the absorption of a photon causes the electron’s spin magnetic moment to flip from the lower energy state to the higher energy state. According to Section 29.5, the change in energy is \( 2\mu_B B \). (The lower energy state corresponds to the case in which the \( z \) component of the magnetic moment \( \mu \) is aligned with the magnetic field, and the higher energy state corresponds to the case in which the \( z \) component of \( \mu \) is aligned opposite to the field.) What is the photon frequency required to excite an ESR transition in a 0.350-T magnetic field?

70. An electron in chromium moves from the \( n = 2 \) state to the \( n = 1 \) state without emitting a photon. Instead, the excess energy is transferred to an outer electron (one in the \( n = 4 \) state), which is then ejected by the atom. In this Auger (pronounced “ohjay”) process, the ejected electron is referred to as an Auger electron. Use the Bohr theory to find the kinetic energy of the Auger electron.

71. The states of matter are solid, liquid, gas, and plasma. Plasma can be described as a gas of charged particles or a gas of ionized atoms. Most of the matter in the Solar System is plasma (throughout the interior of the Sun). In fact, most of the matter in the Universe is plasma; so is a candle flame. Use the information in Figure 42.20 to make an order-of-magnitude estimate for the temperature to which a typical chemical element must be raised to turn into plasma by ionizing most of the atoms in a sample. Explain your reasoning.

72. Show that the wave function for a hydrogen atom in the \( 2s \) state

\[
\psi_2(r) = \frac{1}{4\sqrt{2\pi}} \left( \frac{1}{a_0} \right)^{3/2} \left( 2 - \frac{r}{a_0} \right) e^{-r/2a_0}
\]

satisfies the spherically symmetric Schrödinger equation given in Problem 26.

73. Find the average (expectation) value of \( 1/r \) in the \( 1s \) state of hydrogen. Note that the general expression is given by

\[
\langle 1/r \rangle = \int_{\text{all space}} |\psi|^2 (1/r) \, dV = \int_0^\infty P(r)(1/r) \, dr
\]

Is the result equal to the inverse of the average value of \( r^2 \)?

74. Why is the following situation impossible? An experiment is performed on an atom. Measurements of the atom when it is in a particular excited state show five possible values of the \( z \) component of orbital angular momentum, ranging between \( 3.16 \times 10^{-34} \) kg · m²/s and \( -3.16 \times 10^{-34} \) kg · m²/s.

75. In the Bohr model of the hydrogen atom, an electron travels in a circular path. Consider another case in which an electron travels in a circular path: a single electron moving perpendicular to a magnetic field \( \mathbf{B} \). Lev Davidovich Landau (1908–1968) solved the Schrödinger equation for such an electron. The electron can be considered as a model atom without a nucleus or as the irreducible quantum limit of the cyclotron. Landau proved its energy is quantized in uniform steps of \( eB/qm \). In 1999, a single electron was trapped by a Harvard University research team in an evacuated centimeter-size metal can cooled to a temperature of 80 mK. In a magnetic field of magnitude...
5.26 T, the electron circulated for hours in its lowest energy level. (a) Evaluate the size of a quantum jump in the electron’s energy. (b) For comparison, evaluate \(k_B T\) as a measure of the energy available to the electron in blackbody radiation from the walls of its container. Microwave radiation was introduced to excite the electron. Calculate (c) the frequency and (d) the wavelength of the photon the electron absorbed as it jumped to its second energy level. Measurement of the resonant absorption frequency verified the theory and permitted precise determination of properties of the electron.

76. As the Earth moves around the Sun, its orbits are quantized. (a) Follow the steps of Bohr’s analysis of the hydrogen atom to show that the allowed radii of the Earth’s orbit are given by

\[
r = \frac{n^2 \hbar^2}{GM_S M_E}
\]

where \(n\) is an integer quantum number, \(M_S\) is the mass of the Sun, and \(M_E\) is the mass of the Earth. (b) Calculate the numerical value of \(n\) for the Sun–Earth system. (c) Find the distance between the orbit for quantum number \(n\) and the next orbit out from the Sun corresponding to the quantum number \(n + 1\). (d) Discuss the significance of your results from parts (b) and (c).

77. An elementary theorem in statistics states that the root-mean-square uncertainty in a quantity \(r\) is given by \(\Delta r = \sqrt{\langle r^2 \rangle - \langle r \rangle^2}\). Determine the uncertainty in the radial position of the electron in the ground state of the hydrogen atom. Use the average value of \(r\) found in Example 42.3: \(\langle r \rangle = 3a_0/2\). The average value of the squared distance between the electron and the proton is given by

\[
\langle r^2 \rangle = \int_0^\infty |\psi|^2 r^2 dV = \int_0^\infty P(r) r^2 dr
\]

78. Example 42.3 calculates the most probable value and the average value for the radial coordinate \(r\) of the electron in the ground state of a hydrogen atom. For comparison with these modal and mean values, find the median value of \(r\). Proceed as follows. (a) Derive an expression for the probability, as a function of \(r\), that the electron in the ground state of hydrogen will be found outside a sphere of radius \(r\) centered on the nucleus. (b) Make a graph of the probability as a function of \(r/a_0\). Choose values of \(r/a_0\) ranging from 0 to 4.00 in steps of 0.250. (c) Find the value of \(r\) for which the probability of finding the electron outside a sphere of radius \(r\) is equal to the probability of finding the electron inside this sphere. You must solve a transcendental equation numerically, and your graph is a good starting point.

79. (a) For a hydrogen atom making a transition from the \(n = 4\) state to the \(n = 2\) state, determine the wavelength of the photon created in the process. (b) Assuming the atom was initially at rest, determine the recoil speed of the hydrogen atom when it emits this photon.

80. Astronomers observe a series of spectral lines in the light from a distant galaxy. On the hypothesis that the lines form the Lyman series for a (new?) one-electron atom, they start to construct the energy-level diagram shown in Figure P42.80, which gives the wavelengths of the first four lines and the short-wavelength limit of this series. Based on this information, calculate (a) the energies of the ground state and first four excited states for this one-electron atom and (b) the wavelengths of the first three lines and the short-wavelength limit in the Balmer series for this atom. (c) Show that the wavelengths of the first four lines and the short-wavelength limit of the Lyman series for the hydrogen atom are all 60.0% of the wavelengths for the Lyman series in the one-electron atom in the distant galaxy. (d) Based on this observation, explain why this atom could be hydrogen.

Figure P42.80

We wish to show that the most probable radial position for an electron in the \(2s\) state of hydrogen is \(r = 5.236a_0\).

- **81.** (a) Use Equations 42.24 and 42.26 to find the radial probability density for the \(2s\) state of hydrogen. (b) Calculate the derivative of the radial probability density with respect to \(r\). (c) Set the derivative in part (b) equal to zero and identify three values of \(r\) that represent minima in the function. (d) Find two values of \(r\) that represent maxima in the function. (e) Identify which of the values in part (c) represents the highest probability.

82. All atoms have the same size, to an order of magnitude. (a) To demonstrate this fact, estimate the atomic diameters for aluminum (with molar mass 27.0 g/mol and density 2.70 g/cm\(^3\)) and uranium (molar mass 238 g/mol and density 18.9 g/cm\(^3\)). (b) What do the results of part (a) imply about the wave functions for inner-shell electrons as we progress to higher and higher atomic mass atoms?

83. A pulsed ruby laser emits light at 694.3 nm. For a 14.0-ps pulse containing 3.00 J of energy, find (a) the physical length of the pulse as it travels through space and (b) the number of photons in it. (c) The beam has a circular cross section of diameter 0.600 cm. Find the number of photons per cubic millimeter.

84. A pulsed laser emits light of wavelength \(\lambda\). For a pulse of duration \(\Delta t\) having energy \(E_{IR}\), find (a) the physical length of the pulse as it travels through space and (b) the number of photons in it. (c) The beam has a
circular cross section having diameter $d$. Find the number of photons per unit volume.

85. Assume three identical uncharged particles of mass $m$ and spin $\frac{1}{2}$ are contained in a one-dimensional box of length $L$. What is the ground-state energy of this system?

86. Suppose the ionization energy of an atom is 4.10 eV. In the spectrum of this same atom, we observe emission lines with wavelengths 310 nm, 400 nm, and 1377.8 nm. Use this information to construct the energy-level diagram with the fewest levels. Assume the higher levels are closer together.

87. For hydrogen in the 1s state, what is the probability of finding the electron farther than $2.50 a_0$ from the nucleus?

88. For hydrogen in the 1s state, what is the probability of finding the electron farther than $\beta a_0$ from the nucleus, where $\beta$ is an arbitrary number?

Challenge Problems

89. The positron is the antiparticle to the electron. It has the same mass and a positive electric charge of the same magnitude as that of the electron. Positronium is a hydrogen-like atom consisting of a positron and an electron revolving around each other. Using the Bohr model, find (a) the allowed distances between the two particles and (b) the allowed energies of the system.

90. Review. Steven Chu, Claude Cohen-Tannoudji, and William Phillips received the 1997 Nobel Prize in Physics for “the development of methods to cool and trap atoms with laser light.” One part of their work was with a beam of atoms (mass $\sim 10^{-25}$ kg) that move at a speed on the order of 1 km/s, similar to the speed of molecules in air at room temperature. An intense laser light beam tuned to a visible atomic transition (assume 500 nm) is directed straight into the atomic beam; that is, the atomic beam and the light beam are traveling in opposite directions. An atom in the ground state immediately absorbs a photon. Total system momentum is conserved in the absorption process. After a lifetime on the order of $10^{-8}$ s, the excited atom radiates by spontaneous emission. It has an equal probability of emitting a photon in any direction. Therefore, the average “recoil” of the atom is zero over many absorption and emission cycles. (a) Estimate the average deceleration of the atomic beam. (b) What is the order of magnitude of the distance over which the atoms in the beam are brought to a halt?

91. (a) Use Bohr’s model of the hydrogen atom to show that when the electron moves from the $n$ state to the $n - 1$ state, the frequency of the emitted light is

$$f = \left(\frac{2\pi^2 m k^2 e^4}{\hbar^4}\right) \frac{2n - 1}{n^2(n - 1)^2}$$

(b) Bohr’s correspondence principle claims that quantum results should reduce to classical results in the limit of large quantum numbers. Show that as $n \to \infty$, this expression varies as $1/n^3$ and reduces to the classical frequency one expects the atom to emit. **Suggestions:** To calculate the classical frequency, note that the frequency of revolution is $v/2\pi r$, where $v$ is the speed of the electron and $r$ is given by Equation 42.10.
The most random atomic arrangement, that of a gas, was well understood in the 1800s as discussed in our study of kinetic theory in Chapter 21. In a crystalline solid, the atoms are not randomly arranged; rather, they form a regular array. The symmetry of the arrangement of atoms both stimulated and allowed rapid progress in the field of solid-state physics in the 20th century. Recently, our understanding of liquids and amorphous solids has advanced. (In an amorphous solid such as glass or paraffin, the atoms do not form a regular array.) The recent interest in the physics of low-cost amorphous materials has been driven by their use in such devices as solar cells, memory elements, and fiber-optic waveguides. With the addition of liquids, amorphous solids, and some more exotic forms of matter, such as Bose–Einstein condensates, solid-state physics expanded in the middle of the 20th century to become known as condensed matter physics.

We begin this chapter by studying the aggregates of atoms known as molecules. We describe the bonding mechanisms in molecules, the various modes of molecular excitation, and the radiation emitted or absorbed by molecules. Next, we show how molecules combine to form solids. Then, by examining their energy-level structure, we explain the differences between insulating, conducting, semiconducting, and superconducting materials. The chapter also includes discussions of semiconducting junctions and several semiconductor devices.
43.1 Molecular Bonds

The bonding mechanisms in a molecule are fundamentally due to electric forces between atoms (or ions). Because the electric force is conservative, the forces between atoms in the system of a molecule are related to a potential energy function. A stable molecule is expected at a configuration for which the potential energy function for the molecule has its minimum value. (See Section 7.9.)

A potential energy function that can be used to model a molecule should account for two known features of molecular bonding:

1. The force between atoms is repulsive at very small separation distances. When two atoms are brought close to each other, some of their electron shells overlap, resulting in repulsion between the shells. This repulsion is partly electrostatic in origin and partly the result of the exclusion principle. Because all electrons must obey the exclusion principle, some electrons in the overlapping shells are forced into higher energy states and the system energy increases as if a repulsive force existed between the atoms.
2. At somewhat larger separations, the force between atoms is attractive. If that were not true, the atoms in a molecule would not be bound together.

Taking into account these two features, the potential energy for a system of two atoms can be represented by an expression of the form

$$U(r) = -\frac{A}{r^n} + \frac{B}{r^m}$$  \hspace{1cm} (43.1)

where \( r \) is the internuclear separation distance between the two atoms and \( n \) and \( m \) are small integers. The parameter \( A \) is associated with the attractive force and \( B \) with the repulsive force. Example 7.9 gives one common model for such a potential energy function, the Lennard–Jones potential.

Potential energy versus internuclear separation distance for a two-atom system is graphed in Figure 43.1. At large separation distances between the two atoms, the slope of the curve is positive, corresponding to a net attractive force. At the equilibrium separation distance, the attractive and repulsive forces just balance. At this point, the potential energy has its minimum value and the slope of the curve is zero.

A complete description of the bonding mechanisms in molecules is highly complex because bonding involves the mutual interactions of many particles. In this section, we discuss only some simplified models.

Ionic Bonding

When two atoms combine in such a way that one or more outer electrons are transferred from one atom to the other, the bond formed is called an **ionic bond**. Ionic bonds are fundamentally caused by the Coulomb attraction between oppositely charged ions.

A familiar example of an ionic bond is sodium chloride, NaCl, which is common table salt. Sodium, which has the electronic configuration 1s\(^2\)2s\(^2\)2p\(^6\)3s\(^1\), is ionized relatively easily, giving up its 3s electron to form a Na\(^+\) ion. The energy required to ionize the atom to form Na\(^+\) is 5.1 eV. Chlorine, which has the electronic configuration 1s\(^2\)2s\(^2\)2p\(^5\), is one electron short of the filled-shell structure of argon. If we compare the energy of a system of a free electron and a Cl atom with one in which the electron joins the atom to make the Cl\(^-\) ion, we find that the energy of the ion is lower. When the electron makes a transition from the \( E = 0 \) state to the negative energy state associated with the available shell in the atom, energy is released. This amount of energy is called the **electron affinity** of the atom. For chlorine, the electron affinity is 3.6 eV. Therefore, the energy required to form Na\(^+\) and Cl\(^-\) from isolated atoms is 5.1 – 3.6 = 1.5 eV. It costs 5.1 eV to remove...
the electron from the Na atom, but 3.6 eV of it is gained back when that electron is allowed to join with the Cl atom.

Now imagine that these two charged ions interact with one another to form a NaCl "molecule." The total energy of the NaCl molecule versus internuclear separation distance is graphed in Figure 43.2. At very large separation distances, the energy of the system of ions is 1.5 eV as calculated above. The total energy has a minimum value of 4.2 eV at the equilibrium separation distance, which is approximately 0.24 nm. Hence, the energy required to break the Na⁺—Cl⁻ bond and form neutral sodium and chlorine atoms, called the dissociation energy, is 4.2 eV. The energy of the molecule is lower than that of the system of two neutral atoms. Consequently, it is energetically favorable for the molecule to form: if a lower energy state of a system exists, the system tends to emit energy to achieve this lower energy state. The system of neutral sodium and chlorine atoms can reduce its total energy by transferring energy out of the system (by electromagnetic radiation, for example) and forming the NaCl molecule.

Covalent Bonding

A covalent bond between two atoms is one in which electrons supplied by either one or both atoms are shared by the two atoms. Many diatomic molecules—such as H₂, F₂, and CO—owe their stability to covalent bonds. The bond between two hydrogen atoms can be described by using atomic wave functions. The ground-state wave function for a hydrogen atom (Chapter 42) is

$$\psi_1(r) = \frac{1}{\sqrt{\pi a_0}} e^{-r/a_0}$$

This wave function is graphed in Figure 43.3a for two hydrogen atoms that are far apart. There is very little overlap of the wave functions $\psi_1(r)$ for atom 1, located at $r = 0$, and $\psi_2(r)$ for atom 2, located some distance away. Suppose now the two atoms are close together. As that happens, their wave functions overlap and form the compound wave function $\psi_1(r) + \psi_2(r)$ shown in Figure 43.3b. Notice that the probability amplitude is larger between the atoms than it is on either side of the combination of atoms. As a result, the probability is higher that the electrons associated with the atoms will be located between the atoms than on the outer regions.
of the system. Consequently, the average position of negative charge in the system is halfway between the atoms. This scenario can be modeled as if there were a fixed negative charge between the atoms, exerting attractive Coulomb forces on both nuclei. Therefore, there is an overall attractive force between the atoms, resulting in a covalent bond.

Because of the exclusion principle, the two electrons in the ground state of H₂ must have antiparallel spins. Also because of the exclusion principle, if a third H atom is brought near the H₂ molecule, the third electron would have to occupy a higher energy level, which is not an energetically favorable situation. For this reason, the H₃ molecule is not stable and does not form.

**Van der Waals Bonding**

Ionic and covalent bonds occur between atoms to form molecules or ionic solids, so they can be described as bonds within molecules. Two additional types of bonds, van der Waals bonds and hydrogen bonds, can occur between molecules.

You might think that two neutral molecules would not interact by means of the electric force because they each have zero net charge. They are attracted to each other, however, by weak electrostatic forces called van der Waals forces. Likewise, atoms that do not form ionic or covalent bonds are attracted to each other by van der Waals forces. Noble gas atoms, for example, because of their filled shell structure, do not generally form molecules or bond to each other to form a liquid. Because of van der Waals forces, however, at sufficiently low temperatures at which thermal excitations are negligible, noble gases first condense to liquids and then solidify. (The exception is helium, which does not solidify at atmospheric pressure.)

The van der Waals force results from the following situation. While being electrically neutral, a molecule has a charge distribution with positive and negative centers at different positions in the molecule. As a result, the molecule may act as an electric dipole. (See Section 23.4.) Because of the dipole electric fields, two molecules can interact such that there is an attractive force between them.

There are three types of van der Waals forces. The first type, called the dipole–dipole force, is an interaction between two molecules each having a permanent electric dipole moment. For example, polar molecules such as HCl have permanent electric dipole moments and attract other polar molecules.

The second type, the dipole–induced dipole force, results when a polar molecule having a permanent electric dipole moment induces a dipole moment in a nonpolar molecule. In this case, the electric field of the polar molecule creates the dipole moment in the nonpolar molecule, which then results in an attractive force between the molecules.

The third type is called the dispersion force, an attractive force that occurs between two nonpolar molecules. In this case, although the average dipole moment of a nonpolar molecule is zero, the average of the square of the dipole moment is non-zero because of charge fluctuations. Two nonpolar molecules near each other tend to have dipole moments that are correlated in time so as to produce an attractive van der Waals force.

**Hydrogen Bonding**

Because hydrogen has only one electron, it is expected to form a covalent bond with only one other atom within a molecule. A hydrogen atom in a given molecule can also form a second type of bond between molecules called a hydrogen bond. Let’s use the water molecule H₂O as an example. In the two covalent bonds in this molecule, the electrons from the hydrogen atoms are more likely to be found near the oxygen atom than near the hydrogen atoms, leaving essentially bare protons at the positions of the hydrogen atoms. This unshielded positive charge can be attracted to the negative end of another polar molecule. Because the proton is unshielded by electrons, the negative end of the other molecule can come very close to the proton to form a bond strong enough to form a solid crystalline structure, such as
that of ordinary ice. The bonds within a water molecule are covalent, but the bonds between water molecules in ice are hydrogen bonds.

The hydrogen bond is relatively weak compared with other chemical bonds and can be broken with an input energy of approximately 0.1 eV. Because of this weakness, ice melts at the low temperature of 0°C. Even though this bond is weak, however, hydrogen bonding is a critical mechanism responsible for the linking of biological molecules and polymers. For example, in the case of the DNA (deoxyribonucleic acid) molecule, which has a double-helix structure (Fig. 43.4), hydrogen bonds form by the sharing of a proton between two atoms and create linkages between the turns of the helix.

Quick Quiz 43.1 For each of the following atoms or molecules, identify the most likely type of bonding that occurs between the atoms or between the molecules. Choose from the following list: ionic, covalent, van der Waals, hydrogen. (a) atoms of krypton (b) potassium and chlorine atoms (c) hydrogen fluoride (HF) molecules (d) chlorine and oxygen atoms in a hypochlorite ion (ClO$_2^-$)

43.2 Energy States and Spectra of Molecules

Consider an individual molecule in the gaseous phase of a substance. The energy $E$ of the molecule can be divided into four categories: (1) electronic energy, due to the interactions between the molecule’s electrons and nuclei; (2) translational energy, due to the motion of the molecule’s center of mass through space; (3) rotational energy, due to the rotation of the molecule about its center of mass; and (4) vibrational energy, due to the vibration of the molecule’s constituent atoms:

$$E = E_{el} + E_{trans} + E_{rot} + E_{vib}$$

We explored the roles of translational, rotational, and vibrational energy of molecules in determining the molar specific heats of gases in Sections 21.2 and 21.3. The translational energy is important in kinetic theory, but it is unrelated to internal structure of the molecule, so this molecular energy is unimportant in interpreting molecular spectra. The electronic energy of a molecule is very complex because it involves the interaction of many charged particles, but various techniques have been developed to approximate its values. Although the electronic energies can be studied, significant information about a molecule can be determined by analyzing its quantized rotational and vibrational energy states. Transitions between these states give spectral lines in the microwave and infrared regions of the electromagnetic spectrum, respectively.

Rotational Motion of Molecules

Let’s consider the rotation of a molecule around its center of mass, confining our discussion to the diatomic molecule (Fig. 43.5a) but noting that the same ideas can be extended to polyatomic molecules. A diatomic molecule aligned along a y axis has only two rotational degrees of freedom, corresponding to rotations about the $x$ and $z$ axes passing through the molecule’s center of mass. We discussed the rotation of such a molecule and its contribution to the specific heat of a gas in Section 21.3. If $\omega$ is the angular frequency of rotation about one of these axes, the rotational kinetic energy of the molecule about that axis can be expressed with Equation 10.24:

$$E_{rot} = \frac{1}{2} I \omega^2$$  \hspace{1cm} (43.2)

In this equation, $I$ is the moment of inertia of the molecule about its center of mass, given by

$$I = \left(\frac{m_1 m_2}{m_1 + m_2}\right) r^2 = \mu r^2$$  \hspace{1cm} (43.3)
where \( m_1 \) and \( m_2 \) are the masses of the atoms that form the molecule, \( r \) is the atomic separation, and \( \mu \) is the **reduced mass** of the molecule (see Example 41.5 and Problem 40 in Chapter 41):

\[
\mu = \frac{m_1 m_2}{m_1 + m_2} \tag{43.4}
\]

The magnitude of the molecule’s angular momentum about its center of mass is given by Equation 11.14, \( L = I \omega \), which classically can have any value. Quantum mechanics, however, restricts the molecule to certain quantized rotational frequencies such that the angular momentum of the molecule has the values\(^5\)

\[
L = \sqrt{J(J + 1)} \hbar \quad J = 0, 1, 2, \ldots \tag{43.5}
\]

where \( J \) is an integer called the **rotational quantum number**. Combining Equations 43.5 and 43.2, we obtain an expression for the allowed values of the rotational kinetic energy of the molecule:

\[
E_{\text{rot}} = \frac{1}{2} I \omega^2 = \frac{1}{2} I (\omega)^2 = \frac{L^2}{2I} = \frac{(\sqrt{J(J + 1)}) \hbar)^2}{2I}
\]

\[
E_{\text{rot}} = E_J = \frac{\hbar^2}{2I} J(J + 1) \quad J = 0, 1, 2, \ldots \tag{43.6}
\]

The allowed rotational energies of a diatomic molecule are plotted in Figure 43.5b. As the quantum number \( J \) goes up, the states become farther apart as displayed earlier for rotational energy levels in Figure 21.7.

For most molecules, transitions between adjacent rotational energy levels result in radiation that lies in the microwave range of frequencies \( (f \sim 10^{11} \text{ Hz}) \). When a molecule absorbs a microwave photon, the molecule jumps from a lower rotational energy level to a higher one. The allowed rotational transitions of linear molecules are regulated by the selection rule \( \Delta J = \pm 1 \). Given this selection rule, all absorption lines in the spectrum of a linear molecule correspond to energy separations equal to \( E_J - E_{J-1} \), where \( J = 1, 2, 3, \ldots \). From Equation 43.6, we see that the energies of the absorbed photons are given by

\[
E_{\text{photon}} = \Delta E_{\text{rot}} = E_J - E_{J-1} = \frac{\hbar^2}{2I} [J(J + 1) - (J - 1)J]
\]

\[
E_{\text{photon}} = \frac{\hbar^2}{I} J = \frac{\hbar^2}{4\pi^2 I} J \quad J = 1, 2, 3, \ldots \tag{43.7}
\]

\(^5\)Equation 43.5 is similar to Equation 42.27 for orbital angular momentum in an atom. The relationship between the magnitude of the angular momentum of a system and the associated quantum number is the same as it is in these equations for any system that exhibits rotation as long as the potential energy function for the system is spherically symmetric.
where \( J \) is the rotational quantum number of the higher energy state. Because 
\[ E_{\text{photon}} = hf, \]
where \( f \) is the frequency of the absorbed photon, we see that the
allowed frequency for the transition \( J = 0 \) to \( J = 1 \) is
\[ f_1 = h/4\pi^2I. \]
The frequency corresponding to the \( f = 1 \) to \( f = 2 \) transition is
\( 2f_1 \), and so on. These predictions are in excellent agreement with the observed frequencies.

Quick Quiz 43.2 A gas of identical diatomic molecules absorbs electromagnetic radiation over a wide range of frequencies. Molecule 1 is in the \( J = 0 \) rotation state and makes a transition to the \( J = 1 \) state. Molecule 2 is in the \( J = 2 \) state and makes a transition to the \( J = 3 \) state. Is the ratio of the frequency of the photon that excited molecule 2 to that of the photon that excited molecule 1 equal to
(a) 1, (b) 2, (c) 3, (d) 4, or (e) impossible to determine?

Example 43.1 Rotation of the CO Molecule

The \( J = 0 \) to \( J = 1 \) rotational transition of the CO molecule occurs at a frequency of \( 1.15 \times 10^{13} \) Hz.

(A) Use this information to calculate the moment of inertia of the molecule.

Solution

Conceptualize Imagine that the two atoms in Figure 43.5a are carbon and oxygen. The center of mass of the molecule is not midway between the atoms because of the difference in masses of the C and O atoms.

Categorize The statement of the problem tells us to categorize this example as one involving a quantum-mechanical treatment and to restrict our investigation to the rotational motion of a diatomic molecule.

Analyze Use Equation 43.7 to find the energy of a photon that excites the molecule from the \( J = 0 \) to the \( J = 1 \) rotational level:

\[ E_{\text{photon}} = \frac{h^2}{4\pi^2I}(1) = \frac{h^2}{4\pi^2I} \]

Equate this energy to \( E = hf \) for the absorbed photon and solve for \( I \):

\[ \frac{h^2}{4\pi^2I} = hf \rightarrow I = \frac{h}{4\pi^2f} \]

Substitute the frequency given in the problem statement:

\[ I = \frac{6.626 \times 10^{-34} \text{ J} \cdot \text{s}}{4\pi^2(1.15 \times 10^{13} \text{ s}^{-1})} = 1.46 \times 10^{-46} \text{ kg} \cdot \text{m}^2 \]

(B) Calculate the bond length of the molecule.

Solution

Find the reduced mass \( \mu \) of the CO molecule:

\[ \mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(12 \text{ u})(16 \text{ u})}{12 \text{ u} + 16 \text{ u}} = 6.86 \text{ u} \]

\[ = (6.86 \text{ u}) \left( \frac{1.66 \times 10^{-27} \text{ kg}}{1 \text{ u}} \right) = 1.14 \times 10^{-26} \text{ kg} \]

Solve Equation 43.3 for \( r \) and substitute for the reduced mass and the moment of inertia from part (A):

\[ r = \sqrt{\frac{I}{\mu}} = \sqrt{\frac{1.46 \times 10^{-46} \text{ kg} \cdot \text{m}^2}{1.14 \times 10^{-26} \text{ kg}}} = 1.13 \times 10^{-10} \text{ m} = 0.0113 \text{ nm} \]

Finalize The moment of inertia of the molecule and the separation distance between the atoms are both very small, as expected for a microscopic system.

What if another photon of frequency \( 1.15 \times 10^{13} \) Hz is incident on the CO molecule while that molecule is in the \( J = 1 \) state? What happens?

Answer Because the rotational quantum states are not equally spaced in energy, the \( f = 1 \) to \( f = 2 \) transition does not have the same energy as the \( J = 0 \) to \( J = 1 \) transition. Therefore, the molecule will not be excited to the \( J = 2 \) state. Two
possibilities exist. The photon could pass by the molecule with no interaction, or the photon could induce a stimulated emission, similar to that for atoms and discussed in Section 42.9. In this case, the molecule makes a transition back to the $J = 0$ state and the original photon and a second identical photon leave the scene of the interaction.

**Vibrational Motion of Molecules**

If we consider a molecule to be a flexible structure in which the atoms are bonded together by “effective springs” as shown in Figure 43.6a, we can apply the particle in simple harmonic motion analysis model to the molecule as long as the atoms in the molecule are not too far from their equilibrium positions. Recall from Section 15.3 that the potential energy function for a simple harmonic oscillator is parabolic, varying as the square of the position of the particle relative to the equilibrium position. (See Eq. 15.20 and Fig. 15.9b.) Figure 43.6b shows a plot of potential energy versus atomic separation for a diatomic molecule, where $r_0$ is the equilibrium atomic separation. For separations close to $r_0$, the shape of the potential energy curve closely resembles the parabolic shape of the potential energy function in the particle in simple harmonic motion model.

According to classical mechanics, the frequency of vibration for the system shown in Figure 43.6a is given by Equation 15.14:

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{\mu}} \quad (43.8)$$

where $k$ is the effective spring constant and $\mu$ is the reduced mass given by Equation 43.4. In Section 21.3, we studied the contribution of a molecule’s vibration to the specific heats of gases.

Quantum mechanics predicts that a molecule vibrates in quantized states as described in Section 41.7. The vibrational motion and quantized vibrational energy can be altered if the molecule acquires energy of the proper value to cause a transition between quantized vibrational states. As discussed in Section 41.7, the allowed vibrational energies are

$$E_{vib} = (v + \frac{1}{2}) \hbar \nu \quad v = 0, 1, 2, \ldots \quad (43.9)$$

where $v$ is an integer called the vibrational quantum number. (We used $n$ in Section 41.7 for a general harmonic oscillator, but $v$ is often used for the quantum number when discussing molecular vibrations.) If the system is in the lowest vibrational state, for which $v = 0$, its ground-state energy is $\frac{1}{2} \hbar \nu$. In the first excited vibrational state, $v = 1$ and the energy is $\frac{3}{2} \hbar \nu$, and so on.

![Figure 43.6](image-url) (a) Effective-spring model of a diatomic molecule. (b) Plot of the potential energy of a diatomic molecule versus atomic separation distance. Compare with Figure 15.11a.
Substituting Equation 43.8 into Equation 43.9 gives the following expression for the allowed vibrational energies:

\[
E_{\text{vib}} = \left( \nu + \frac{1}{2} \right) \frac{\hbar}{2\pi} \sqrt{\frac{k}{\mu}} \quad \nu = 0, 1, 2, \ldots
\]  

(43.10)

The selection rule for the allowed vibrational transitions is \( \Delta \nu = \pm 1 \). Transitions between vibrational levels are caused by absorption of photons in the infrared region of the spectrum. The energy of an absorbed photon is equal to the energy difference between any two successive vibrational levels. Therefore, the photon energy is given by

\[
E_{\text{photon}} = \Delta E_{\text{vib}} = \frac{\hbar}{2\pi} \sqrt{\frac{k}{\mu}}
\]  

(43.11)

The vibrational energies of a diatomic molecule are plotted in Figure 43.7. At ordinary temperatures, most molecules have vibrational energies corresponding to the \( \nu = 0 \) state because the spacing between vibrational states is much greater than \( k_B T \), where \( k_B \) is Boltzmann’s constant and \( T \) is the temperature.

Quick Quiz 43.3 A gas of identical diatomic molecules absorbs electromagnetic radiation over a wide range of frequencies. Molecule 1, initially in the \( \nu = 0 \) vibrational state, makes a transition to the \( \nu = 1 \) state. Molecule 2, initially in the \( \nu = 2 \) state, makes a transition to the \( \nu = 3 \) state. What is the ratio of the frequency of the photon that excited molecule 2 to that of the photon that excited molecule 1? (a) 1 (b) 2 (c) 3 (d) 4 (e) impossible to determine

Example 43.2 Vibration of the CO Molecule

The frequency of the photon that causes the \( \nu = 0 \) to \( \nu = 1 \) transition in the CO molecule is \( 6.42 \times 10^{13} \) Hz. We ignore any changes in the rotational energy for this example.

(A) Calculate the force constant \( k \) for this molecule.

Solution

**Conceptualize** Imagine that the two atoms in Figure 43.6a are carbon and oxygen. As the molecule vibrates, a given point on the imaginary spring is at rest. This point is not midway between the atoms because of the difference in masses of the C and O atoms.

**Categorize** The statement of the problem tells us to categorize this example as one involving a quantum-mechanical treatment and to restrict our investigation to the vibrational motion of a diatomic molecule. The molecule is analyzed with portions of the particle in simple harmonic motion analysis model.
In general, a molecule vibrates and rotates simultaneously. To a first approximation, these motions are independent of each other, so the total energy of the molecule for these motions is the sum of Equations 43.6 and 43.9:

$$E = \frac{\hbar}{2\pi} \sqrt{\frac{k}{\mu}} = hf \rightarrow k = 4\pi^2(1.14 \times 10^{-26} \text{ kg})(6.42 \times 10^{13} \text{ s}^{-1})^2 = 1.85 \times 10^3 \text{ N/m}$$

The energy levels of any molecule can be calculated from this expression, and each level is indexed by the two quantum numbers $v$ and $J$.

From these calculations, an energy-level diagram like the one shown in Figure 43.8a (page 1350) can be constructed. For each allowed value of the vibrational quantum number $v$, there is a complete set of rotational levels corresponding to $J = 0, 1, 2, \ldots$. The energy separation between successive rotational levels is much smaller than the separation between successive vibrational levels. As noted earlier, most molecules at ordinary temperatures are in the $v = 0$ vibrational state; these molecules can be in various rotational states as Figure 43.8a shows.

When a molecule absorbs a photon with the appropriate energy, the vibrational quantum number $v$ increases by one unit while the rotational quantum number $J$ either increases or decreases by one unit as can be seen in Figure 43.8. Therefore, the molecular absorption spectrum in Figure 43.8b consists of two groups of lines: one group to the right of center and satisfying the selection rules $\Delta J = +1$ and $\Delta v = +1$, and the other group to the left of center and satisfying the selection rules $\Delta J = -1$ and $\Delta v = +1$.

The energies of the absorbed photons can be calculated from Equation 43.12:

$$E_{\text{photon}} = \Delta E = hf + \frac{\hbar^2}{J}(J + 1) \quad J = 0, 1, 2, \ldots \quad (\Delta J = +1) \quad (43.13)$$

$$E_{\text{photon}} = \Delta E = hf - \frac{\hbar^2}{J} J \quad J = 1, 2, 3, \ldots \quad (\Delta J = -1) \quad (43.14)$$
where \( J \) is the rotational quantum number of the initial state. Equation 43.13 generates the series of equally spaced lines higher than the frequency \( f \), whereas Equation 43.14 generates the series lower than this frequency. Adjacent lines are separated in frequency by the fundamental unit \( \hbar/2\pi I \). Figure 43.8b shows the expected frequencies in the absorption spectrum of the molecule; these same frequencies appear in the emission spectrum.

The experimental absorption spectrum of the HCl molecule shown in Figure 43.9 follows this pattern very well and reinforces our model. One peculiarity is apparent, however: each line is split into a doublet. This doubling occurs because two chlorine isotopes (Cl-35 and Cl-37; see Section 44.1) were present in the sample used to obtain this spectrum. Because the isotopes have different masses, the two HCl molecules have different values of \( I \).

The intensity of the spectral lines in Figure 43.9 follows an interesting pattern, rising first as one moves away from the central gap (located at about \( 8.65 \times 10^{13} \) Hz, corresponding to the forbidden \( J = 0 \) to \( J = 0 \) transition) and then falling. This intensity is determined by a product of two functions of \( J \). The first function corresponds to the number of available states for a given value of \( J \). This function is \( 2J + 1 \), corresponding to the number of values of \( m_J \), the molecular rotation analog to \( m_l \) for atomic states. For example, the \( J = 2 \) state has five substates with five values of \( m_J (m_J = -2, -1, 0, 1, 2) \), whereas the \( J = 1 \) state has only three substates \( (m_J = -1, 0, 1) \). Therefore, on average and without regard for the second function described below, five-thirds as many molecules make the transition from the \( J = 2 \) state as from the \( J = 1 \) state.

The second function determining the envelope of the intensity of the spectral lines is the Boltzmann factor, introduced in Section 21.5. The number of molecules in an excited rotational state is given by

\[
n = n_0 e^{-\frac{\hbar}{k_B T}(J + 1/2)}
\]

where \( n_0 \) is the number of molecules in the \( J = 0 \) state.

Multiplying these factors together indicates that the intensity of spectral lines should be described by a function of \( J \) as follows:

\[
I \propto (2J + 1) e^{-\frac{\hbar}{k_B T}(J + 1/2)}
\]

(43.15)
The factor \( (2J + 1) \) increases with \( J \) while the exponential second factor decreases. The product of the two factors gives a behavior that closely describes the envelope of the spectral lines in Figure 43.9.

The excitation of rotational and vibrational energy levels is an important consideration in current models of global warming. Most of the absorption lines for CO\(_2\) are in the infrared portion of the spectrum. Therefore, visible light from the Sun is not absorbed by atmospheric CO\(_2\) but instead strikes the Earth’s surface, warming it. In turn, the surface of the Earth, being at a much lower temperature than the Sun, emits thermal radiation that peaks in the infrared portion of the electromagnetic spectrum (Section 40.1). This infrared radiation is absorbed by the CO\(_2\) molecules in the air instead of radiating out into space. Atmospheric CO\(_2\) acts like a one-way valve for energy from the Sun and is responsible, along with some other atmospheric molecules, for raising the temperature of the Earth’s surface above its value in the absence of an atmosphere. This phenomenon is commonly called the “greenhouse effect.” The burning of fossil fuels in today’s industrialized society adds more CO\(_2\) to the atmosphere. This addition of CO\(_2\) increases the absorption of infrared radiation, raising the Earth’s temperature further. In turn, this increase in temperature causes substantial climatic changes.

As seen in Figure 43.10, the amount of carbon dioxide in the atmosphere has been steadily increasing since the middle of the 20th century. This graph shows hard data that indicate that the atmosphere is undergoing a distinct change, although not all scientists agree on the interpretation of what that change means in terms of global temperatures.

The Intergovernmental Panel on Climate Change (IPCC) is a scientific body that assesses the available information related to global warming and associated effects.
related to climate change. It was originally established in 1988 by two United Nations organizations, the World Meteorological Organization and the United Nations Environment Programme. The IPCC has published four assessment reports on climate change, the most recent in 2007, and a fifth report is scheduled to be released in 2014. The 2007 report concludes that there is a probability of greater than 90% that the increased global temperature measured by scientists is due to the placement of greenhouse gases such as carbon dioxide in the atmosphere by humans. The report also predicts a global temperature increase between 1°C and 6°C in the 21st century, a sea level rise from 18 cm to 59 cm, and very high probabilities of weather extremes, including heat waves, droughts, cyclones, and heavy rainfall.

In addition to its scientific aspects, global warming is a social issue with many facets. These facets encompass international politics and economics, because global warming is a worldwide problem. Changing our policies requires real costs to solve the problem. Global warming also has technological aspects, and new methods of manufacturing, transportation, and energy supply must be designed to slow down or reverse the increase in temperature.

Conceptual Example 43.3 Comparing Figures 43.8 and 43.9

In Figure 43.8a, the transitions indicated correspond to spectral lines that are equally spaced as shown in Figure 43.8b. The actual spectrum in Figure 43.9, however, shows lines that move closer together as the frequency increases. Why does the spacing of the actual spectral lines differ from the diagram in Figure 43.8?

Solution

In Figure 43.8, we modeled the rotating diatomic molecule as a rigid object (Chapter 10). In reality, however, as the molecule rotates faster and faster, the effective spring in Figure 43.6a stretches and provides the increased force associated with the larger centripetal acceleration of each atom. As the molecule stretches along its length, its moment of inertia \( J \) increases. Therefore, the rotational part of the energy expression in Equation 43.12 has an extra dependence on \( J \) in the moment of inertia \( I \). Because the increasing moment of inertia is in the denominator, as \( J \) increases, the energies do not increase as rapidly with \( J \) as indicated in Equation 43.12. With each higher energy level being lower than indicated by Equation 43.12, the energy associated with a transition to that level is smaller, as is the frequency of the absorbed photon, destroying the even spacing of the spectral lines and giving the spacing that decreases with increasing frequency seen in Figure 43.9.

43.3 Bonding in Solids

A crystalline solid consists of a large number of atoms arranged in a regular array, forming a periodic structure. The ions in the NaCl crystal are ionically bonded, as already noted, and the carbon atoms in diamond form covalent bonds with one another. The metallic bond described at the end of this section is responsible for the cohesion of copper, silver, sodium, and other solid metals.

Ionic Solids

Many crystals are formed by ionic bonding, in which the dominant interaction between ions is the Coulomb force. Consider a portion of the NaCl crystal shown in Figure 43.11a. The red spheres are sodium ions, and the blue spheres are chlorine ions. As shown in Figure 43.11b, each Na⁺ ion has six nearest-neighbor Cl⁻ ions. Similarly, in Figure 43.11c, we see that each Cl⁻ ion has six nearest-neighbor Na⁺ ions. Each Na⁺ ion is attracted to its six Cl⁻ neighbors. The corresponding potential energy is \(-6ke^2/r\), where \( k \) is the Coulomb constant and \( r \) is the separation distance between each Na⁺ and Cl⁻. In addition, there are 12 next-nearest-neighbor
Na\(^+\) ions at a distance of \(\sqrt{2}r\) from the Na\(^+\) ion, and these 12 positive ions exert weaker repulsive forces on the central Na\(^+\) ion. Furthermore, beyond these 12 Na\(^+\) ions are more Cl\(^-\) ions that exert an attractive force, and so on. The net effect of all these interactions is a resultant negative electric potential energy

\[
U_{\text{attractive}} = -\alpha k_e \frac{e^2}{r}
\]

where \(\alpha\) is a dimensionless number known as the Madelung constant. The value of \(\alpha\) depends only on the particular crystalline structure of the solid. For example, \(\alpha = 1.747\) for the NaCl structure. When the constituent ions of a crystal are brought close together, a repulsive force exists because of electrostatic forces and the exclusion principle as discussed in Section 43.1. The potential energy term \(B/r^m\) in Equation 43.1 accounts for this repulsive force. We do not include neighbors other than nearest neighbors here because the repulsive forces occur only for ions that are very close together. (Electron shells must overlap for exclusion-principle effects to become important.) Therefore, we can express the total potential energy of the crystal as

\[
U_{\text{total}} = -\alpha k_e \frac{e^2}{r} + \frac{B}{r^m}
\]

where \(m\) in this expression is some small integer.

A plot of total potential energy versus ion separation distance is shown in Figure 43.12. The potential energy has its minimum value \(U_0\) at the equilibrium separation, when \(r = r_0\). It is left as a problem (Problem 59) to show that

\[
U_0 = -\alpha k_e \frac{e^2}{r_0} \left(1 - \frac{1}{m}\right)
\]

This minimum energy \(U_0\) is called the ionic cohesive energy of the solid, and its absolute value represents the energy required to separate the solid into a collection of isolated positive and negative ions. Its value for NaCl is \(-7.84\) eV per ion pair.

To calculate the atomic cohesive energy, which is the binding energy relative to the energy of the neutral atoms, 5.14 eV must be added to the ionic cohesive energy value to account for the transition from Na\(^+\) to Na and 3.62 eV must be subtracted to account for the conversion of Cl\(^-\) to Cl. Therefore, the atomic cohesive energy of NaCl is

\[
-7.84\text{ eV} + 5.14\text{ eV} - 3.62\text{ eV} = -6.32\text{ eV}
\]

In other words, 6.32 eV of energy per ion pair is needed to separate the solid into isolated neutral atoms of Na and Cl.
Ionic crystals form relatively stable, hard crystals. They are poor electrical conductors because they contain no free electrons; each electron in the solid is bound tightly to one of the ions, so it is not sufficiently mobile to carry current. Ionic crystals have high melting points; for example, the melting point of NaCl is 801°C. Ionic crystals are transparent to visible radiation because the shells formed by the electrons in ionic solids are so tightly bound that visible radiation does not possess sufficient energy to promote electrons to the next allowed shell. Infrared radiation is absorbed strongly because the vibrations of the ions have natural resonant frequencies in the low-energy infrared region.

**Covalent Solids**

Solid carbon, in the form of diamond, is a crystal whose atoms are covalently bonded. Because atomic carbon has the electronic configuration \(1s^22s^22p^2\), it is four electrons short of filling its \(n = 2\) shell, which can accommodate eight electrons. Because of this electron structure, two carbon atoms have a strong attraction for each other, with a cohesive energy of 7.37 eV. In the diamond structure, each carbon atom is covalently bonded to four other carbon atoms located at four corners of a cube as shown in Figure 43.13a.

The crystalline structure of diamond is shown in Figure 43.13b. Notice that each carbon atom forms covalent bonds with four nearest-neighbor atoms. The basic structure of diamond is called tetrahedral (each carbon atom is at the center of a regular tetrahedron), and the angle between the bonds is 109.5°. Other crystals such as silicon and germanium have the same structure.

Carbon is interesting in that it can form several different types of structures. In addition to the diamond structure, it forms graphite, with completely different properties. In this form, the carbon atoms form flat layers with hexagonal arrays of atoms. A very weak interaction between the layers allows the layers to be removed easily under friction, as occurs in the graphite used in pencil lead.

Carbon atoms can also form a large hollow structure; in this case, the compound is called buckminsterfullerene after the famous architect R. Buckminster Fuller, who invented the geodesic dome. The unique shape of this molecule (Fig. 43.14) provides a “cage” to hold other atoms or molecules. Related structures, called “buckytubes” because of their long, narrow cylindrical arrangements of carbon atoms, may provide the basis for extremely strong, yet lightweight, materials.

A current area of active research is in the properties and applications of graphene. Graphene consists of a monolayer of carbon atoms, with the atoms arranged in hexagons so that the monolayer looks like chicken wire. Graphite flakes that are shed from a pencil while writing contain small fragments of graphene. Pioneers in graphene research include Andre Geim (b. 1958) and Konstantin Novoselov (b. 1974) of the University of Manchester, who received the Nobel Prize in Physics in 2010 for their experiments. Graphene has interesting electronic, thermal, and optical properties that are currently under investigation. Its mechanical properties include a breaking strength 200 times that of steel. Potential applications under
study include graphene nanoribbons, quantum dots, transistors, optical modulators, and integrated circuits.

The atomic cohesive energies of some covalent solids are given in Table 43.1. The large energies account for the hardness of covalent solids. Diamond is particularly hard and has an extremely high melting point (about 4,000 K). Covalently bonded solids usually have high bond energies and high melting points, and are good electrical insulators.

### Metallic Solids

Metallic bonds are generally weaker than ionic or covalent bonds. The outer electrons in the atoms of a metal are relatively free to move throughout the material, and the number of such mobile electrons in a metal is large. The metallic structure can be viewed as a “sea” or a “gas” of nearly free electrons surrounding a lattice of positive ions (Fig. 43.15). The bonding mechanism in a metal is the attractive force between the entire collection of positive ions and the electron gas. Metals have a cohesive energy in the range of 1 to 3 eV per atom, which is less than the cohesive energies of ionic or covalent solids.

Light interacts strongly with the free electrons in metals. Hence, visible light is absorbed and re-emitted quite close to the surface of a metal, which accounts for the shiny nature of metal surfaces. In addition to the high electrical conductivity of metals produced by the free electrons, the nondirectional nature of the metallic bond allows many different types of metal atoms to be dissolved in a host metal in varying amounts. The resulting solid solutions, or alloys (steel, bronze, brass, etc.), may be designed to have particular properties, such as tensile strength, ductility, electrical and thermal conductivity, and resistance to corrosion.

Because the bonding in metals is between all the electrons and all the positive ions, metals tend to bend when stressed. This bending is in contrast to nonmetallic solids, which tend to fracture when stressed. Fracturing results because bonding in nonmetallic solids is primarily with nearest-neighbor ions or atoms. When the distortion causes sufficient stress between some set of nearest neighbors, fracture occurs.

### 43.4 Free-Electron Theory of Metals

In Section 27.3, we described a classical free-electron theory of electrical conduction in metals, a structural model that led to Ohm’s law. According to this theory, a metal is modeled as a classical gas of conduction electrons moving through a fixed lattice of ions. Although this theory predicts the correct functional form of Ohm’s law, it does not predict the correct values of electrical and thermal conductivities.

A quantum-based free-electron theory of metals remedies the shortcomings of the classical model by taking into account the wave nature of the electrons. In this model, based on the quantum particle under boundary conditions analysis model, the outer-shell electrons are free to move through the metal but are trapped within...
a three-dimensional box formed by the metal surfaces. Therefore, each electron is represented as a particle in a box. As discussed in Section 41.2, particles in a box are restricted to quantized energy levels.

Statistical physics can be applied to a collection of particles in an effort to relate microscopic properties to macroscopic properties as we saw with kinetic theory of gases in Chapter 21. In the case of electrons, it is necessary to use quantum statistics, with the requirement that each state of the system can be occupied by only two electrons (one with spin up and the other with spin down) as a consequence of the exclusion principle. The probability that a particular state having energy \( E \) is occupied by one of the electrons in a solid is

\[
f(E) = \frac{1}{e^{(E-E_F)/k_B T} + 1}
\]

where \( f(E) \) is called the Fermi–Dirac distribution function and \( E_F \) is called the Fermi energy. A plot of \( f(E) \) versus \( E \) at \( T = 0 \) K is shown in Figure 43.16a. Notice that \( f(E) = 1 \) for \( E < E_F \) and \( f(E) = 0 \) for \( E > E_F \). That is, at 0 K, all states having energies less than the Fermi energy are occupied and all states having energies greater than the Fermi energy are vacant. A plot of \( f(E) \) versus \( E \) at some temperature \( T > 0 \) K is shown in Figure 43.16b. This curve shows that as \( T \) increases, the distribution rounds off slightly. Because of thermal excitation, states near and below \( E_F \) lose population and states near and above \( E_F \) gain population. The Fermi energy \( E_F \) also depends on temperature, but the dependence is weak in metals.

Let’s now follow up on our discussion of the particle in a box in Chapter 41 to generalize the results to a three-dimensional box. Recall that if a particle of mass \( m \) is confined to move in a one-dimensional box of length \( L \), the allowed states have quantized energy levels given by Equation 41.14:

\[
E_n = \left( \frac{\hbar^2}{8mL^2} \right) n^2 = \left( \frac{\hbar^2\pi^2}{2mL^2} \right) n^2 \quad n = 1, 2, 3, \ldots
\]

Now imagine a piece of metal in the shape of a solid cube of sides \( L \) and volume \( L^3 \) and focus on one electron that is free to move anywhere in this volume. Therefore, the electron is modeled as a particle in a three-dimensional box. In this model, we require that \( \psi(x, y, z) = 0 \) at the boundaries of the metal. It can be shown (see Problem 37) that the energy for such an electron is

\[
E = \frac{\hbar^2\pi^2}{2m_eL^2} \left( n_x^2 + n_y^2 + n_z^2 \right)
\]

where \( m_e \) is the mass of the electron and \( n_x, n_y, \) and \( n_z \) are quantum numbers. As we expect, the energies are quantized, and each allowed value of the energy is characterized by this set of three quantum numbers (one for each degree of freedom) and the spin quantum number \( m_s \). For example, the ground state, corresponding to
\( n_s = n_g = n_z = 1 \), has an energy equal to \( 3\hbar^2 \pi^2 / 2m_i L^2 \) and can be occupied by two electrons, corresponding to spin up and spin down.

Because of the macroscopic size \( L \) of the box, the energy levels for the electrons are very close together. As a result, we can treat the quantum numbers as continuous variables. Under this assumption, the number of allowed states per unit volume that have energies between \( E \) and \( E + dE \) is

\[
g(E) \, dE = \frac{8\sqrt{2} \pi m_e^{3/2}}{h^3} E^{1/2} \, dE \quad (43.21)
\]

(See Example 43.5.) The function \( g(E) \) is called the density-of-states function.

If a metal is in thermal equilibrium, the number of electrons per unit volume \( N(E) \) \( dE \) that have energy between \( E \) and \( E + dE \) is equal to the product of the number of allowed states per unit volume and the probability that a state is occupied; that is, \( N(E) \, dE = g(E) f(E) \, dE \):

\[
N(E) \, dE = \left( \frac{8\sqrt{2} \pi m_e^{3/2}}{h^3} E^{1/2} \right) \left( \frac{1}{e^{(E-E_F)/k_B T} + 1} \right) \, dE \quad (43.22)
\]

Plots of \( N(E) \) versus \( E \) for two temperatures are given in Figure 43.17.

If \( n_e \) is the total number of electrons per unit volume, we require that

\[
n_e = \int_{E_F}^{\infty} N(E) \, dE = \int_{0}^{\infty} \frac{8\sqrt{2} \pi m_e^{3/2}}{h^3} \frac{E^{1/2}}{e^{(E-E_F)/k_B T} + 1} \, dE \quad (43.23)
\]

We can use this condition to calculate the Fermi energy. At \( T = 0 \) K, the Fermi-Dirac distribution function \( f(E) = 1 \) for \( E < E_F \) and \( f(E) = 0 \) for \( E > E_F \). Therefore, at \( T = 0 \) K, Equation 43.23 becomes

\[
n_e = \frac{8\sqrt{2} \pi m_e^{3/2}}{h^3} \int_{0}^{E_F} E^{1/2} \, dE = \frac{1}{3} \frac{8\sqrt{2} \pi m_e^{3/2}}{h^3} E_F^{3/2} \quad (43.24)
\]

Solving for the Fermi energy at 0 K gives

\[
E_F(0) = \frac{\hbar^2}{2m_e} \left( \frac{3n_e}{8\pi} \right)^{2/3} \quad (43.25)
\]

The Fermi energies for metals are in the range of a few electron volts. Representative values for various metals are given in Table 43.2. It is left as a problem (Problem 39) to show that the average energy of a free electron in a metal at 0 K is

\[
E_{\text{avg}} = \frac{3}{2} E_F \quad (43.26)
\]

In summary, we can consider a metal to be a system comprising a very large number of energy levels available to the free electrons. These electrons fill the levels in accordance with the Pauli exclusion principle, beginning with \( E = 0 \) and ending with \( E_F \). At \( T = 0 \) K, all levels below the Fermi energy are filled and all levels above the Fermi energy are empty. At 300 K, a small fraction of the free electrons are excited above the Fermi energy.

Example 43.4  The Fermi Energy of Gold

Each atom of gold (Au) contributes one free electron to the metal. Compute the Fermi energy for gold.

**Solution**

Conceptualize  Imagine electrons filling available levels at $T = 0 \text{ K}$ in gold until the solid is neutral. The highest energy filled is the Fermi energy.

Categorize  We evaluate the result using a result from this section, so we categorize this example as a substitution problem.

Substitute the concentration of free electrons in gold from Table 43.2 into Equation 43.25 to calculate the Fermi energy at 0 K:

$$E_F(0) = \left( \frac{6.626 \times 10^{-34} \text{ J s}}{2(9.11 \times 10^{-31} \text{ kg})} \right)^{2/3} \left[ \frac{3(5.90 \times 10^{28} \text{ m}^{-3})}{8 \pi} \right]^{2/3}$$

$$= 8.85 \times 10^{-19} \text{ J} = 5.53 \text{ eV}$$

Example 43.5  Deriving Equation 43.21

Based on the allowed states of a particle in a three-dimensional box, derive Equation 43.21.

**Solution**

Conceptualize  Imagine a particle confined to a three-dimensional box, subject to boundary conditions in three dimensions. Imagine also a three-dimensional quantum number space whose axes represent $n_x$, $n_y$, and $n_z$. The allowed states in this space can be represented as dots located at integral values of the three quantum numbers as in Figure 43.18. This space is not traditional space in which a location is specified by coordinates $x$, $y$, and $z$; rather, it is a space in which allowed states can be specified by coordinates representing the quantum numbers. The number of allowed states having energies between $E$ and $E + dE$ corresponds to the number of dots in the spherical shell of radius $n$ and thickness $dn$.

Categorize  We categorize this problem as that of a quantum system in which the energies of the particle are quantized. Furthermore, we can base the solution to the problem on our understanding of the particle in a one-dimensional box.

Analyze  As noted previously, the allowed states of the particle in a three-dimensional box are described by three quantum numbers $n_x$, $n_y$, and $n_z$. For a macroscopic sample of metal, the number of allowed values of these quantum numbers is tremendous, so on a macroscopic scale, the allowed states in the number space can be modeled as continuous.

Defining $E_0 = \frac{\hbar^2 \pi^2}{2mL^2}$ and $n = (E/E_0)^{1/2}$, rewrite Equation 43.20:

$$n_x^2 + n_y^2 + n_z^2 = \frac{2mL^2}{\hbar^2 \pi^2} E = \frac{E}{E_0} = n^2$$

In the quantum number space, Equation (1) is the equation of a sphere of radius $n$. Therefore, the number of allowed states having energies between $E$ and $E + dE$ is equal to the number of points in a spherical shell of radius $n$ and thickness $dn$.

Find the “volume” of this shell, which represents the total number of states $G(E) \, dE$:

$$G(E) \, dE = \frac{1}{4} \pi n^2 \, dn = \frac{1}{2} \pi n^2 \, dn$$

We have taken one-eighth of the total volume because we are restricted to the octant of a three-dimensional space in which all three quantum numbers are positive.

Replace $n$ in Equation (2) with its equivalent in terms of $E$ using the relation $n^2 = E/E_0$ from Equation (1):

$$G(E) \, dE = \frac{1}{2} \pi \left( \frac{E}{E_0} \right) \, \left[ \frac{E}{E_0} \right]^{1/2} \, d\left[ \left( \frac{E}{E_0} \right)^{1/2} \right] = \frac{1}{2} \pi \left( \frac{E}{E_0} \right)^{3/2} \, d\left[ \left( \frac{E}{E_0} \right)^{1/2} \right]$$
Evaluate the differential:

\[ G(E) \, dE = \frac{1}{2} \left[ \frac{E}{(E_0)^{3/2}} \right] (4E^{1/2} \, dE) = \frac{1}{2} \pi E_0^{-3/2} E^{1/2} \, dE \]

Substitute for \( E_0 \) from its definition above:

\[ G(E) \, dE = \frac{1}{2} \pi \left( \frac{\hbar^2 \pi^2}{2m_e L^2} \right)^{-3/2} E^{1/2} \, dE \]

Letting \( g(E) \) represent the number of states per unit volume, where \( L^3 \) is the volume \( V \) of the cubical box in normal space, find \( g(E) = G(E)/V \):

\[ g(E) \, dE = \frac{G(E)}{V} \, dE = \frac{\sqrt{2}}{2} \frac{m_e^{3/2}}{\hbar^3 \pi^2} E^{1/2} \, dE \]

Substitute \( \hbar = \hbar/2\pi \):

\[ g(E) \, dE = \frac{4\sqrt{2}}{2} \frac{\pi m_e^{3/2}}{\hbar^3} E^{1/2} \, dE \]

Multiply by 2 for the two possible spin states in each particle-in-a-box state:

\[ g(E) \, dE = \frac{8\sqrt{2}}{2} \frac{\pi m_e^{3/2}}{\hbar^3} E^{1/2} \, dE \]

Finalize This result is Equation 43.21, which is what we set out to derive.

### 43.5 Band Theory of Solids

In Section 43.4, the electrons in a metal were modeled as particles free to move around inside a three-dimensional box and we ignored the influence of the parent atoms. In this section, we make the model more sophisticated by incorporating the contribution of the parent atoms that form the crystal.

Recall from Section 41.1 that the probability density \( |\psi|^2 \) for a system is physically significant, but the probability amplitude \( \psi \) is not. Let’s consider as an example an atom that has a single s electron outside of a closed shell. Both of the following wave functions are valid for such an atom with atomic number \( Z \):

\[ \psi_s^r (r) = \pm Af(r) e^{-Zr/\hbar \alpha_n} \]

where \( A \) is the normalization constant and \( f(r) \) is a function of \( r \) that varies with the value of \( n \). Choosing either of these wave functions leads to the same value of \(|\psi|^2\), so both choices are equivalent. A difference arises, however, when two atoms are combined.

If two identical atoms are very far apart, they do not interact and their electronic energy levels can be considered to be those of isolated atoms. Suppose the two atoms are sodium, each having a lone 3s electron that is in a well-defined quantum state. As the two sodium atoms are brought closer together, their wave functions begin to overlap as we discussed for covalent bonding in Section 43.1. The properties of the combined system differ depending on whether the two atoms are combined with wave functions \( \psi_s^r (r) \) as in Figure 43.19a or whether they are combined with one having wave function \( \psi_1^r (r) \) and the other \( \psi_2^- (r) \) as in Figure 43.19b. The choice of two atoms with wave function \( \psi_s^r (r) \) is physically equivalent to that with two positive wave functions, so we do not consider it separately. When two wave functions \( \psi_s^r (r) \) are combined, the result is a composite wave function in which the probability amplitudes add between the atoms. If \( \psi_1^r (r) \) combines with \( \psi_2^- (r) \),

---

The probability of an electron being between the atoms is nonzero.

(a) Two atoms with wave functions \( \psi_s^r (r) \) combine.

(b) Two atoms with wave functions \( \psi_1^r (r) \) and \( \psi_2^- (r) \) combine.

---

*The functions \( f(r) \) are called Laguerre polynomials. They can be found in the quantum treatment of the hydrogen atom in modern physics textbooks.*
however, the wave functions between the nuclei subtract. Therefore, the composite probability amplitudes for the two possibilities are different. These two possible combinations of wave functions represent two possible states of the two-atom system. We interpret these curves as representing the probability amplitude of finding an electron. The positive–positive curve shows some probability of finding the electron at the midpoint between the atoms. The positive–negative function shows no such probability. A state with a high probability of an electron being between two positive nuclei must have a different energy than a state with a high probability of the electron being elsewhere! Therefore, the states are split into two energy levels due to the two ways of combining the wave functions. The energy difference is relatively small, so the two states are close together on an energy scale.

Figure 43.20 shows this splitting effect as a function of separation distance. For large separations \( r \), the electron clouds do not overlap and there is no splitting. As the atoms are brought closer so that \( r \) decreases, the electron clouds overlap and we need to consider the system of two atoms.

When a large number of atoms are brought together to form a solid, a similar phenomenon occurs. The individual wave functions can be brought together in various combinations of \( \psi_1^+(r) \) and \( \psi_1^-(r) \), each possible combination corresponding to a different energy. As the atoms are brought close together, the various isolated-atom energy levels split into multiple energy levels for the composite system. This splitting in levels for five atoms in close proximity is shown in Figure 43.20b. In this case, there are five energy levels corresponding to five different combinations of isolated-atom wave functions.

As the number of atoms grows, the number of combinations of wave functions grows, as does the number of possible energies. If we extend this argument to the large number of atoms found in solids (on the order of \( 10^{23} \) atoms per cubic centimeter), we obtain a huge number of levels of varying energy so closely spaced that they may be regarded as a continuous band of energy levels as shown in Figure 43.20c. In the case of sodium, it is customary to refer to the continuous distributions of allowed energy levels as a band of energy levels as shown in Figure 43.20c. In the case of sodium, it is customary to refer to the continuous distributions of allowed energy levels as \( s \) bands because the bands originate from the \( s \) levels of the individual sodium atoms.

Each energy level in the atom can spread into a band when the atoms are combined into a solid. Figure 43.21 shows the allowed energy bands of sodium at a fixed separation distance between the atoms. Notice that energy gaps, corresponding to forbidden energies, occur between the allowed bands. In addition, some bands exhibit sufficient spreading in energy that there is an overlap between bands arising from different quantum states (\( 3s \) and \( 3p \)).
43.6 Electrical Conduction in Metals, Insulators, and Semiconductors

Good electrical conductors contain a high density of free charge carriers, and the density of free charge carriers in insulators is nearly zero. Semiconductors, first introduced in Section 23.2, are a class of technologically important materials in which charge-carrier densities are intermediate between those of insulators and those of conductors. In this section, we discuss the mechanisms of conduction in these three classes of materials in terms of a model based on energy bands.

Metals

If a material is to be a good electrical conductor, the charge carriers in the material must be free to move in response to an applied electric field. Let’s consider the electrons in a metal as the charge carriers. The motion of the electrons in response to an electric field represents an increase in energy of the system (the metal lattice and the free electrons) corresponding to the additional kinetic energy of the moving electrons. The system is described by the nonisolated system model for energy. Equation 8.2 becomes \( W = D \Delta K \), where the work is done on the electrons by the electric field. Therefore, when an electric field is applied to a conductor, electrons must move upward to an available higher energy state on an energy-level diagram to represent the additional kinetic energy.

Figure 43.22 shows a half-filled band in a metal at \( T = 0 \) K, where the blue region represents levels filled with electrons. Because electrons obey Fermi–Dirac statistics, all levels below the Fermi energy are filled with electrons and all levels above the Fermi energy are empty. The Fermi energy lies in the band at the highest filled state. At temperatures slightly greater than 0 K, some electrons are thermally excited to levels above \( E_F \), but overall there is little change from the 0 K case. If a potential difference is applied to the metal, however, electrons having energies near the Fermi energy require only a small amount of additional energy from the applied electric field to reach nearby empty energy states above the Fermi energy. Therefore, electrons in a metal experiencing only a weak applied electric field are free to move because many empty levels are available close to the occupied energy levels. The model of metals based on band theory demonstrates that metals are excellent electrical conductors.

Insulators

Now consider the two outermost energy bands of a material in which the lower band is filled with electrons and the higher band is empty at 0 K (Fig. 43.23).
lower, filled band is called the **valence band**, and the upper, empty band is the **conduction band**. (The conduction band is the one that is partially filled in a metal.) It is common to refer to the energy separation between the valence and conduction bands as the **energy gap** $E_g$ of the material. The Fermi energy lies somewhere in the energy gap as shown in Figure 43.23.

Suppose a material has a relatively large energy gap of, for example, approximately 5 eV. At 300 K (room temperature), $k_B T = 0.025$ eV, which is much smaller than the energy gap. At such temperatures, the Fermi–Dirac distribution predicts that very few electrons are thermally excited into the conduction band. There are no available states that lie close in energy above the valence band and into which electrons can move upward to account for the extra kinetic energy associated with motion through the material in response to an electric field. Consequently, the electrons do not move; the material is an insulator. Although an insulator has many vacant states in its conduction band that can accept electrons, these states are separated from the filled states by a large energy gap. Only a few electrons occupy these states, so the overall electrical conductivity of insulators is very small.

### Semiconductors

Semiconductors have the same type of band structure as an insulator, but the energy gap is much smaller, on the order of 1 eV. Table 43.3 shows the energy gaps for some representative materials. The band structure of a semiconductor is shown in Figure 43.24. Because the Fermi level is located near the middle of the gap for a semiconductor and $E_g$ is small, appreciable numbers of electrons are thermally excited from the valence band to the conduction band. Because of the many empty levels above the thermally filled levels in the conduction band, a small applied potential difference can easily raise the electrons in the conduction band into available energy states, resulting in a moderate current.

At $T = 0$ K, all electrons in these materials are in the valence band and no energy is available to excite them across the energy gap. Therefore, semiconductors are poor conductors at very low temperatures. Because the thermal excitation of electrons across the narrow gap is more probable at higher temperatures, the conductivity of semiconductors increases rapidly with temperature, contrasting sharply with the conductivity of metals, which decreases slowly with increasing temperature.

Charge carriers in a semiconductor can be negative, positive, or both. When an electron moves from the valence band into the conduction band, it leaves behind a vacant site, called a **hole**, in the otherwise filled valence band. This hole (electron-deficient site) acts as a charge carrier in the sense that a free electron from a nearby site can transfer into the hole. Whenever an electron does so, it creates a new hole at the site it abandoned. Therefore, the net effect can be viewed as the hole migrating through the material in the direction opposite the direction of electron movement. The hole behaves as if it were a particle with a positive charge $+e$.

A pure semiconductor crystal containing only one element or one compound is called an **intrinsic semiconductor**. In these semiconductors, there are equal numbers of conduction electrons and holes. Such combinations of charges are called **electron–hole pairs**. In the presence of an external electric field, the holes move in the direction of the field and the conduction electrons move in the direction opposite the field (Fig. 43.25). Because the electrons and holes have opposite signs, both motions correspond to a current in the same direction.

---

\*We defined the Fermi energy as the energy of the highest filled state at $T = 0$, which might suggest that the Fermi energy should be at the top of the valence band in Figure 43.23. A more sophisticated general treatment of the Fermi energy, however, shows that it is located at that energy at which the probability of occupation is one-half (see Fig. 43.16b). According to this definition, the Fermi energy lies in the energy gap between the bands.
Quick Quiz 43.4 Consider the data on three materials given in the table.

Identify each material as a conductor, an insulator, or a semiconductor.

Doped Semiconductors

When impurities are added to a semiconductor, both the band structure of the semiconductor and its resistivity are modified. The process of adding impurities, called doping, is important in controlling the conductivity of semiconductors. For example, when an atom containing five outer-shell electrons, such as arsenic, is added to a Group IV semiconductor, four of the electrons form covalent bonds with atoms of the semiconductor and one is left over (Fig. 43.26a). This extra electron is nearly free of its parent atom and can be modeled as having an energy level that lies in the energy gap, immediately below the conduction band (Fig. 43.26b). Such a pentavalent atom in effect donates an electron to the structure and hence is referred to as a donor atom. Because the spacing between the energy level of the electron of the donor atom and the bottom of the conduction band is very...
small (typically, approximately 0.05 eV), only a small amount of thermal excitation is needed to cause this electron to move into the conduction band. (Recall that the average energy of an electron at room temperature is approximately $k_B T \approx 0.025$ eV.) Semiconductors doped with donor atoms are called \textit{n-type semiconductors} because the majority of charge carriers are electrons, which are negatively charged.

If a Group IV semiconductor is doped with atoms containing three outer-shell electrons, such as indium and aluminum, the three electrons form covalent bonds with neighboring semiconductor atoms, leaving an electron deficiency—a hole—where the fourth bond would be if an impurity-atom electron were available to form it (Fig. 43.27a). This situation can be modeled by placing an energy level in the energy gap, immediately above the valence band, as in Figure 43.27b. An electron from the valence band has enough energy at room temperature to fill this impurity level, leaving behind a hole in the valence band. This hole can carry current in the presence of an electric field. Because a trivalent atom accepts an electron from the valence band, such impurities are referred to as \textit{acceptor atoms}. A semiconductor doped with trivalent (acceptor) impurities is known as a \textit{p-type semiconductor} because the majority of charge carriers are \textit{positively} charged holes.

When conduction in a semiconductor is the result of acceptor or donor impurities, the material is called an \textit{extrinsic semiconductor}. The typical range of doping densities for extrinsic semiconductors is $10^{13}$ to $10^{19}$ cm$^{-3}$, whereas the electron density in a typical semiconductor is roughly $10^{21}$ cm$^{-3}$.

\section*{43.7 Semiconductor Devices}

The electronics of the first half of the 20th century was based on vacuum tubes, in which electrons pass through empty space between a cathode and an anode. We have seen vacuum tube devices in Figure 29.6 (the television picture tube), Figure 29.10 (circular electron beam), Figure 29.15a (Thomson’s apparatus for measuring $e/m$ for the electron), and Figure 40.9 (photoelectric effect apparatus).

The transistor was invented in 1948, leading to a shift away from vacuum tubes and toward semiconductors as the basis of electronic devices. This phase of electronics has been under way for several decades. As discussed in Chapter 41, there may be a new phase of electronics in the near future using nanotechnological devices employing quantum dots and other nanoscale structures.
In this section, we discuss electronic devices based on semiconductors, which are still in wide use and will be for many years to come.

**The Junction Diode**

A fundamental unit of a semiconductor device is formed when a $p$-type semiconductor is joined to an $n$-type semiconductor to form a $p-n$ junction. A **junction diode** is a device that is based on a single $p-n$ junction. The role of a diode of any type is to pass current in one direction but not the other. Therefore, it acts as a one-way valve for current.

The $p-n$ junction shown in Figure 43.28a consists of three distinct regions: a $p$ region, an $n$ region, and a small area that extends several micrometers to either side of the interface, called a **depletion region**.

The depletion region may be visualized as arising when the two halves of the junction are brought together. The mobile $n$-side donor electrons nearest the junction (deep-blue area in Fig. 43.28a) diffuse to the $p$ side and fill holes located there, leaving behind immobile positive ions. While this process occurs, we can model the holes that are being filled as diffusing to the $n$ side, leaving behind a region (brown area in Fig. 43.28a) of fixed negative ions.

Because the two sides of the depletion region each carry a net charge, an internal electric field on the order of $10^4$ to $10^6$ V/cm exists in the depletion region (see Fig. 43.28b). This field produces an electric force on any remaining mobile charge carriers that sweeps them out of the depletion region, so named because it is a region depleted of mobile charge carriers. This internal electric field creates an internal potential difference $\Delta V_0$ that prevents further diffusion of holes and electrons across the junction and thereby ensures zero current in the junction when no potential difference is applied.

Figure 43.28  (a) Physical arrangement of a $p-n$ junction. (b) Component $E_x$ of the internal electric field versus $x$ for the $p-n$ junction. (c) Internal electric potential difference $\Delta V$ versus $x$ for the $p-n$ junction.
The operation of the junction as a diode is easiest to understand in terms of the potential difference graph shown in Figure 43.28. If a voltage $V_D$ is applied to the junction such that the $p$-side is connected to the positive terminal of a voltage source as shown in Figure 43.29a, the internal potential difference $V_0$ across the junction decreases as shown at the top of the figure; the decrease results in a current that increases exponentially with increasing forward voltage, or forward bias. For reverse bias (where the $n$-side of the junction is connected to the positive terminal of a voltage source), the internal potential difference $V_0$ increases with increasing reverse bias as in Figure 43.29b; the increase results in a very small reverse current that quickly reaches a saturation value $I_0$. The current–voltage relationship for an ideal diode is

$$I = I_0 \left( e^{\frac{V_D}{kT}} - 1 \right)$$

where the first $e$ is the base of the natural logarithm, the second $e$ represents the magnitude of the electron charge, $k_B$ is Boltzmann's constant, and $T$ is the absolute temperature. Figure 43.29c shows an $I-V$ plot characteristic of a real $p-n$ junction, demonstrating the diode behavior.

Light-Emitting and Light-Absorbing Diodes

Light-emitting diodes (LEDs) and semiconductor lasers are common examples of devices that depend on the behavior of semiconductors. LEDs are used in LCD television displays, household lighting, flashlights, and camera flash units. Semiconductor lasers are often used for pointers in presentations and in playback equipment for digitally recorded information.

Light emission and absorption in semiconductors is similar to light emission and absorption by gaseous atoms except that in the discussion of semiconductors we must incorporate the concept of energy bands rather than the discrete energy levels in single atoms. As shown in Figure 43.30a, an electron excited electrically into the conduction band can easily recombine with a hole (especially if the electron is injected into a $p$ region). As this recombination takes place, a photon of energy $E_g$ is emitted. With proper design of the semiconductor and the associated plastic envelope or mirrors, the light from a large number of these transitions serves as the source of an LED or a semiconductor laser.

Conversely, an electron in the valence band may absorb an incoming photon of light and be promoted to the conduction band, leaving a hole behind (Fig. 43.30b). This absorbed energy can be used to operate an electrical circuit.

One device that operates on this principle is the photovoltaic solar cell, which appears in many handheld calculators. An early large-scale application of arrays of
Estimate the band gap of the semiconductor in the infrared LED of a typical television remote control.

SOLUTION

Conceptualize Imagine electrons in Figure 43.30a falling from the conduction band to the valence band, emitting infrared photons in the process.

Categorize We use concepts discussed in this section, so we categorize this example as a substitution problem.

In Chapter 34, we learned that the wavelength of infrared light ranges from 700 nm to 1 mm. Let’s pick a number that is easy to work with, such as 1 000 nm (which is not a bad estimate because remote controls typically operate in the range of 880 to 950 nm.)

Estimate the energy $h\nu$ of the photons from the remote control:

$$E = h\nu = \frac{hc}{\lambda} = \frac{1.240 \text{ eV} \cdot \text{nm}}{1000 \text{ nm}} = 1.2 \text{ eV}$$

This value corresponds to an energy gap $E_g$ of approximately 1.2 eV in the LED’s semiconductor.
The Transistor

The invention of the transistor by John Bardeen (1908–1991), Walter Brattain (1902–1987), and William Shockley (1910–1989) in 1948 totally revolutionized the world of electronics. For this work, these three men shared the Nobel Prize in Physics in 1956. By 1960, the transistor had replaced the vacuum tube in many electronic applications. The advent of the transistor created a multitrillion-dollar industry that produces such popular devices as personal computers, wireless keyboards, smartphones, electronic book readers, and computer tablets.

A junction transistor consists of a semiconducting material in which a very narrow n region is sandwiched between two p regions or a p region is sandwiched between two n regions. In either case, the transistor is formed from two p–n junctions. These types of transistors were used widely in the early days of semiconductor electronics.

During the 1960s, the electronics industry converted many electronic applications from the junction transistor to the field-effect transistor, which is much easier to manufacture and just as effective. Figure 43.31a shows the structure of a very common device, the MOSFET, or metal-oxide-semiconductor field-effect transistor. You are likely using millions of MOSFET devices when you are working on your computer.

There are three metal connections (the M in MOSFET) to the transistor: the source, drain, and gate. The source and drain are connected to n-type semiconductor regions (the S in MOSFET) at either end of the structure. These regions are connected by a narrow channel of additional n-type material, the n channel. The source and drain regions and the n channel are embedded in a p-type substrate material, which forms a depletion region, as in the junction diode, along the bottom of the n channel. (Depletion regions also exist at the junctions underneath the source and drain regions, but we will ignore them because the operation of the device depends primarily on the behavior in the channel.)

The gate is separated from the n channel by a layer of insulating silicon dioxide (the O in MOSFET, for oxide). Therefore, it does not make electrical contact with the rest of the semiconducting material.

Imagine that a voltage source $V_{SD}$ is applied across the source and drain as shown in Figure 43.31b. In this situation, electrons flow through the upper region of the n channel. Electrons cannot flow through the depletion region in the lower part of the n channel because this region is depleted of charge carriers. Now a second voltage $V_{SG}$ is applied across the source and gate as in Figure 43.31c. The positive potential on the gate electrode results in an electric field below the gate that is directed downward in the n channel (the field in “field-effect”). This electric field exerts upward forces on electrons in the region below the gate, causing them to move into the n channel. Consequently, the depletion region becomes smaller.

---

**Figure 43.31** (a) The structure of a metal-oxide-semiconductor field-effect transistor (MOSFET). (b) A source–drain voltage is applied. (c) A gate voltage is applied.
widening the area through which there is current between the top of the $n$ channel and the depletion region. As the area becomes wider, the current increases.

If a varying voltage, such as that generated from music stored in the memory of a smartphone, is applied to the gate, the area through which the source–drain current exists varies in size according to the varying gate voltage. A small variation in gate voltage results in a large variation in current and a correspondingly large voltage across the resistor in Figure 43.31c. Therefore, the MOSFET acts as a voltage amplifier. A circuit consisting of a chain of such transistors can result in a very small initial signal from a microphone being amplified enough to drive powerful speakers at an outdoor concert.

The Integrated Circuit

Invented independently by Jack Kilby (1923–2005, Nobel Prize in Physics, 2000) at Texas Instruments in late 1958 and by Robert Noyce (1927–1990) at Fairchild Camera and Instrument in early 1959, the integrated circuit has been justly called "the most remarkable technology ever to hit mankind." Kilby’s first device is shown in Figure 43.32. Integrated circuits have indeed started a “second industrial revolution” and are found at the heart of computers, watches, cameras, automobiles, aircraft, robots, space vehicles, and all sorts of communication and switching networks.

In simplest terms, an integrated circuit is a collection of interconnected transistors, diodes, resistors, and capacitors fabricated on a single piece of silicon known as a chip. Contemporary electronic devices often contain many integrated circuits (Fig. 43.33). State-of-the-art chips easily contain several million components within a 1-cm$^2$ area, and the number of components per square inch has increased steadily since the integrated circuit was invented. The dramatic advances in chip technology can be seen by looking at microchips manufactured by Intel. The 4004 chip, introduced in 1971, contained 2,300 transistors. This number increased to 3.2 million 24 years later in 1995 with the Pentium processor. Sixteen years later, the Core i7 Sandy Bridge processor introduced in November 2011 contained 2.27 billion transistors.

Integrated circuits were invented partly to solve the interconnection problem spawned by the transistor. In the era of vacuum tubes, power and size considerations of individual components set modest limits on the number of components that could be interconnected in a given circuit. With the advent of the tiny, low-power, highly reliable transistor, design limits on the number of components disappeared and were replaced by the problem of wiring together hundreds of thousands of components. The magnitude of this problem can be appreciated when we consider that second-generation computers (consisting of discrete transistors rather than integrated circuits) contained several hundred thousand components requiring more than a million joints that had to be hand-soldered and tested.

In addition to solving the interconnection problem, integrated circuits possess the advantages of miniaturization and fast response, two attributes critical for high-speed computers. Because the response time of a circuit depends on the time
interval required for electrical signals traveling at the speed of light to pass from one component to another, miniaturization and close packing of components result in fast response times.

### 43.8 Superconductivity

We learned in Section 27.5 that there is a class of metals and compounds known as **superconductors** whose electrical resistance decreases to virtually zero below a certain temperature \( T_c \) called the **critical temperature** (Table 27.3). Let’s now look at these amazing materials in greater detail, using what we know about the properties of solids to help us understand the behavior of superconductors.

Let’s start by examining the Meissner effect, introduced in Section 30.6 as the exclusion of magnetic flux from the interior of superconductors. The Meissner effect is illustrated in Figure 43.34 for a superconducting material in the shape of a long cylinder. Notice that the magnetic field penetrates the cylinder when its temperature is greater than \( T_c \) (Fig. 43.34a). As the temperature is lowered to below \( T_c \), however, the field lines are spontaneously expelled from the interior of the superconductor (Fig. 43.34b). Therefore, a superconductor is more than a perfect conductor (resistivity \( \rho = 0 \)); it is also a perfect diamagnet (\( B = 0 \)). The property that \( B = 0 \) in the interior of a superconductor is as fundamental as the property of zero resistance. If the magnitude of the applied magnetic field exceeds a critical value \( B_c \), defined as the value of \( B \) that destroys a material’s superconducting properties, the field again penetrates the sample.

Because a superconductor is a perfect diamagnet, it repels a permanent magnet. In fact, one can perform a demonstration of the Meissner effect by floating a small permanent magnet above a superconductor and achieving magnetic levitation as seen in Figure 30.27 in Section 30.6.

Recall from our study of electricity that a good conductor expels static electric fields by moving charges to its surface. In effect, the surface charges produce an electric field that exactly cancels the externally applied field inside the conductor. In a similar manner, a superconductor expels magnetic fields by forming surface currents. To see why that happens, consider again the superconductor shown in Figure 43.34. Let’s assume the sample is initially at a temperature \( T > T_c \) (Fig. 43.34a) so that the magnetic field penetrates the cylinder. As the cylinder is cooled to a temperature \( T < T_c \), the field is expelled as shown in Figure 43.34b. Surface currents induced on the superconductor’s surface produce a magnetic field that exactly cancels the externally applied field inside the superconductor. As you would expect, the surface currents disappear when the external magnetic field is removed.

A successful theory for superconductivity in metals was published in 1957 by John Bardeen, L. N. Cooper (b. 1930), and J. R. Schrieffer (b. 1931); it is generally called BCS theory, based on the first letters of their last names. This theory led to a Nobel Prize in Physics for the three scientists in 1972. In this theory, two electrons can interact via distortions in the array of lattice ions so that there is a net attractive force between the electrons.\(^5\) As a result, the two electrons are bound into an entity called a **Cooper pair**, which behaves like a particle with integral spin. Particles with integral spin are called **bosons**. (As noted in Pitfall Prevention 42.6, fermions make up another class of particles, those with half-integral spin.) An important feature of bosons is that they do not obey the Pauli exclusion principle. Consequently, at very low temperatures, it is possible for all bosons in a collection of such particles to be in the lowest quantum state. The entire collection of Cooper pairs in the metal is described by a single wave function. Above the energy level associated with this wave function is an energy gap equal to the binding energy of a Cooper pair. Under

\(^5\)A highly simplified explanation of this attraction between electrons is as follows. The attractive Coulomb force between one electron and the surrounding positively charged lattice ions causes the ions to move inward slightly toward the electron. As a result, there is a higher concentration of positive charge in this region than elsewhere in the lattice. A second electron is attracted to the higher concentration of positive charge.
the action of an applied electric field, the Cooper pairs experience an electric force and move through the metal. A random scattering event of a Cooper pair from a lattice ion would represent resistance to the electric current. Such a collision would change the energy of the Cooper pair because some energy would be transferred to the lattice ion. There are no available energy levels below that of the Cooper pair (it is already in the lowest state), however, and none available above because of the energy gap. As a result, collisions do not occur and there is no resistance to the movement of Cooper pairs.

An important development in physics that elicited much excitement in the scientific community was the discovery of high-temperature copper oxide-based superconductors. The excitement began with a 1986 publication by J. Georg Bednorz (b. 1950) and K. Alex Müller (b. 1927), scientists at the IBM Zurich Research Laboratory in Switzerland. In their seminal paper, Bednorz and Müller reported strong evidence for superconductivity at 30 K in an oxide of barium, lanthanum, and copper. They were awarded the Nobel Prize in Physics in 1987 for their remarkable discovery. Shortly thereafter, a new family of compounds was open for investigation and research activity in the field of superconductivity proceeded vigorously. In early 1987, groups at the University of Alabama at Huntsville and the University of Houston announced superconductivity at approximately 92 K in an oxide of yttrium, barium, and copper (YBa$_2$Cu$_3$O$_7$). Later that year, teams of scientists from Japan and the United States reported superconductivity at 105 K in an oxide of bismuth, strontium, calcium, and copper. Superconductivity at temperatures as high as 150 K have been reported in an oxide containing mercury. In 2006, Japanese scientists discovered superconductivity for the first time in iron-based materials, beginning with LaFePO, with a critical temperature of 4 K. The highest critical temperature that has been reported so far in the iron-based materials is 55 K, a milestone held by fluorine-doped SmFeAsO. These newly discovered materials have rejuvenated the field of high-$T_c$ superconductivity. Today, one cannot rule out the possibility of room-temperature superconductivity, and the mechanisms responsible for the behavior of high-temperature superconductors are still under investigation. The search for novel superconducting materials continues both for scientific reasons and because practical applications become more probable and widespread as the critical temperature is raised.

Although BCS theory was very successful in explaining superconductivity in metals, there is currently no widely accepted theory for high-temperature superconductivity. It remains an area of active research.

---

**Concepts and Principles**

Two or more atoms combine to form molecules because of a net attractive force between the atoms. The mechanisms responsible for molecular bonding can be classified as follows:

- **Ionic bonds** form primarily because of the Coulomb attraction between oppositely charged ions. Sodium chloride (NaCl) is one example.
- **Covalent bonds** form when the constituent atoms of a molecule share electrons. For example, the two electrons of the $\text{H}_2$ molecule are equally shared between the two nuclei.
- **Van der Waals bonds** are weak electrostatic bonds between molecules or between atoms that do not form ionic or covalent bonds. These bonds are responsible for the condensation of noble gas atoms and nonpolar molecules into the liquid phase.
- **Hydrogen bonds** form between the center of positive charge in a polar molecule that includes one or more hydrogen atoms and the center of negative charge in another polar molecule.

---

The allowed values of the rotational energy of a diatomic molecule are

\[ E_{\text{rot}} = \frac{\hbar^2}{2I} J(J + 1) \quad J = 0, 1, 2, \ldots \quad (43.6) \]

where \( I \) is the moment of inertia of the molecule and \( J \) is an integer called the rotational quantum number. The selection rule for transitions between rotational states is \( \Delta J = \pm 1 \).

The allowed values of the vibrational energy of a diatomic molecule are

\[ E_{\text{vib}} = \frac{\hbar^2}{2\mu} \sqrt{v} \quad v = 0, 1, 2, \ldots \quad (43.10) \]

where \( v \) is the vibrational quantum number, \( \mu \) is the reduced mass of the molecule. The selection rule for allowed vibrational transitions is \( \Delta v = \pm 1 \), and the energy difference between any two adjacent levels is the same, regardless of which two levels are involved.

In the free-electron theory of metals, the free electrons fill the quantized levels in accordance with the Pauli exclusion principle. The number of states per unit volume available to the conduction electrons having energies between \( E \) and \( E + dE \) is

\[ N(E) \, dE = \left( \frac{8\sqrt{2} \pi m_{e}^{3/2}}{\hbar^2} \right) \left( \frac{1}{e^{(E-E_{F})/k_{B}T} + 1} \right) \, dE \quad (43.22) \]

where \( E_{F} \) is the Fermi energy. At \( T = 0 \) K, all levels below \( E_{F} \) are filled, all levels above \( E_{F} \) are empty, and

\[ E_{F}(0) = \frac{\hbar^2}{2m_{e}} \left( \frac{3n_{e}}{8\pi} \right)^{2/3} \quad (43.25) \]

where \( n_{e} \) is the total number of conduction electrons per unit volume. Only those electrons having energies near \( E_{F} \) can contribute to the electrical conductivity of the metal.

Bonding mechanisms in solids can be classified in a manner similar to the schemes for molecules. For example, the Na\(^+\) and Cl\(^-\) ions in NaCl form ionic bonds, whereas the carbon atoms in diamond form covalent bonds. The metallic bond is characterized by a net attractive force between positive ion cores and the mobile free electrons of a metal.

In a crystalline solid, the energy levels of the system form a set of bands. Electrons occupy the lowest energy states, with no more than one electron per state. Energy gaps are present between the bands of allowed states.

A semiconductor is a material having an energy gap of approximately 1 eV and a valence band that is filled at \( T = 0 \) K. Because of the small energy gap, a significant number of electrons can be thermally excited from the valence band into the conduction band. The band structures and electrical properties of a Group IV semiconductor can be modified by the addition of either donor atoms containing five outer-shell electrons or acceptor atoms containing three outer-shell electrons. A semiconductor doped with donor impurity atoms is called an n-type semiconductor, and one doped with acceptor impurity atoms is called a p-type semiconductor.

Objective Questions

1. Is each one of the following statements true or false for a superconductor below its critical temperature? (a) It can carry infinite current. (b) It must carry some non-zero current. (c) Its interior electric field must be zero. (d) Its internal magnetic field must be zero. (e) No internal energy appears when it carries electric current.

2. An infrared absorption spectrum of a molecule is shown in Figure OQ43.2. Notice that the highest peak on either side of the gap is the third peak from the gap. After this spectrum is taken, the temperature of the sample of molecules is raised to a much higher value. Compared with Figure OQ43.2, in this new spectrum is the highest absorption peak (a) at the same frequency, (b) farther from the gap, or (c) closer to the gap?

3. What kind of bonding likely holds the atoms together in the following solids (i), (ii), and (iii)? Choose your answer available in Student Solutions Manual/Study Guide.
Conceptual Questions

1. The energies of photons of visible light range between the approximate values 1.8 eV and 3.1 eV. Explain why silicon, with an energy gap of 1.14 eV at room temperature (see Table 43.3), appears opaque, whereas diamond, with an energy gap of 5.47 eV, appears transparent.

2. Discuss the three major forms of excitation of a molecule (other than translational motion) and the relative energies associated with these three forms.

3. How can the analysis of the rotational spectrum of a molecule lead to an estimate of the size of that molecule?

4. Pentavalent atoms such as arsenic are donor atoms in a semiconductor such as silicon, whereas trivalent atoms such as indium are acceptors. Inspect the periodic table in Appendix C and determine what other elements might make good donors or acceptors.

5. When a photon is absorbed by a semiconductor, an electron–hole pair is created. Give a physical explanation of this statement using the energy-band model as the basis for your description.

6. (i) Should you expect an $n$-type doped semiconductor to have (a) higher, (b) lower, or (c) the same conductivity as an intrinsic (pure) semiconductor? (ii) Should you expect a $p$-type doped semiconductor to have (a) higher, (b) lower, or (c) the same conductivity as an intrinsic (pure) semiconductor?

7. Consider a typical material composed of covalently bonded diatomic molecules. Rank the following energies from the largest in magnitude to the smallest in magnitude. (a) the latent heat of fusion per molecule (b) the molecular binding energy (c) the energy of the first excited state of molecular rotation (d) the energy of the first excited state of molecular vibration.

8. As discussed in Chapter 27, the conductivity of metals decreases with increasing temperature due to electron collisions with vibrating atoms. In contrast, the conductivity of semiconductors increases with increasing temperature. What property of a semiconductor is responsible for this behavior? (a) Atomic vibrations decrease as temperature increases. (b) The number of conduction electrons and the number of holes increase steeply with increasing temperature. (c) The energy gap decreases with increasing temperature. (d) Electrons do not collide with atoms in a semiconductor.

9. The Fermi energy for silver is 5.48 eV. In a piece of solid silver, free-electron energy levels are measured near 2 eV and near 6 eV. (i) Near which of these energies are the energy levels closer together? (a) 2 eV (b) 6 eV (c) The spacing is the same. (ii) Near which of these energies are more electrons occupying energy levels? (a) 2 eV (b) 6 eV (c) The number of electrons is the same.

10. As discussed in Chapter 27, the conductivity of metals decreases with increasing temperature due to electron collisions with vibrating atoms. In contrast, the conductivity of semiconductors increases with increasing temperature. What property of a semiconductor is responsible for this behavior? (a) Atomic vibrations decrease as temperature increases. (b) The number of conduction electrons and the number of holes increase steeply with increasing temperature. (c) The energy gap decreases with increasing temperature. (d) Electrons do not collide with atoms in a semiconductor.
Section 43.1 Molecular Bonds

1. A van der Waals dispersion force between helium atoms produces a very shallow potential well, with a depth on the order of 1 meV. At approximately what temperature would you expect helium to condense?

2. Review. A K⁺ ion and a Cl⁻ ion are separated by a distance of 5.00 \times 10^{-10} \text{ m}. Assuming the two ions act like charged particles, determine (a) the force each ion exerts on the other and (b) the potential energy of the two-ion system in electron volts.

3. Potassium chloride is an ionic bonded molecule that is sold as a salt substitute for use in a low-sodium diet. Potassium chloride is an ionically bonded molecule that is sold as a salt substitute for use in a low-sodium diet. The electron affinity of chlorine is 3.6 eV. What is the electron affinity of K?

4. In the potassium iodide (KI) molecule, assume the K and I atoms bond ionically by the transfer of one electron from K to I. (a) The ionization energy of K is 4.34 eV, and the electron affinity of I is 3.06 eV. What energy is needed to transfer an electron from K to I, to form K⁺ and Cl⁻ ions from separate K and Cl atoms? This quantity is sometimes called the activation energy \( E_a \). (b) A model potential energy function for the KI molecule is the Lennard-Jones potential:

\[
U(r) = 4\epsilon \left[ \left( \frac{\sigma}{r} \right)^{12} - 2 \left( \frac{\sigma}{r} \right)^6 \right] + E_a
\]

where \( r \) is the internuclear separation distance and \( \epsilon \) and \( \sigma \) are adjustable parameters. The \( E_a \) term is added to ensure the correct asymptotic behavior at large \( r \). At the equilibrium separation distance, \( r = r_0 = 0.305 \text{ nm} \), \( U(r) \) is a minimum, and \( dU/dr = 0 \). In addition, \( U(r_0) \) is the negative of the dissociation energy: \( U(r_0) = -3.37 \text{ eV} \). Find \( \sigma \) and \( \epsilon \). (c) Calculate the force needed to break up a KI molecule. (d) Calculate the force constant for small oscillations about \( r = r_0 \). Suggestion: Set \( r = r_0 + s \), where \( s/r_0 \ll 1 \), and expand \( U(r) \) in powers of \( s/r_0 \) up to second-order terms.

5. One description of the potential energy of a diatomic molecule is given by the Lennard-Jones potential,

\[
U = \frac{A}{r^{12}} - \frac{B}{r^6}
\]

where \( A \) and \( B \) are constants and \( r \) is the separation distance between the atoms. For the H₂ molecule, take \( A = 0.124 \times 10^{-120} \text{ eV} \cdot \text{ m}^6 \) and \( B = 1.488 \times 10^{-60} \text{ eV} \cdot \text{ m}^6 \). Find (a) the separation distance \( r_0 \) at which the energy of the molecule is a minimum and (b) the energy \( E \) required to break up the H₂ molecule.

6. One description of the potential energy of a diatomic molecule is given by the Lennard-Jones potential,

\[
U = \frac{A}{r^{12}} - \frac{B}{r^6}
\]

where \( A \) and \( B \) are constants and \( r \) is the separation distance between the atoms. Find, in terms of \( A \) and \( B \), (a) the value \( r_0 \) at which the energy is a minimum and (b) the energy \( E \) required to break up a diatomic molecule.

Section 43.2 Energy States and Spectra of Molecules

7. The CO molecule makes a transition from the \( J = 1 \) to the \( J = 2 \) rotational state when it absorbs a photon of frequency 2.30 \times 10^{13} \text{ Hz}. (a) Find the moment of inertia of this molecule from these data. (b) Compare your answer with that obtained in Example 43.1 and comment on the significance of the two results.

8. The cesium iodide (CsI) molecule has an atomic separation of 0.127 nm. (a) Determine the energy of the second excited rotational state, with \( J = 2 \). (b) Find the frequency of the photon absorbed in the \( J = 1 \) to \( J = 2 \) transition.

9. An HCl molecule is excited to its second rotational energy level, corresponding to \( J = 2 \). If the distance between its nuclei is 0.127 5 nm, what is the angular speed of the molecule about its center of mass?

10. The photon frequency that would be absorbed by the NO molecule in a transition from vibration state \( v = 0 \) to \( v = 1 \), with no change in rotation state, is 56.3 THz. The bond between the atoms has an effective spring constant of 1 550 N/m. (a) Use this information to calculate the reduced mass of the NO molecule. (b) Compute a value for \( \mu \) using Equation 43.4. (c) Compare your results to parts (a) and (b) and explain their difference, if any.

11. Assume the distance between the protons in the H₂ molecule is 0.750 \times 10^{-10} \text{ m}. (a) Find the energy of the first excited rotational state, with \( J = 1 \). (b) Find the wavelength of radiation emitted in the transition from \( J = 1 \) to \( J = 0 \).

12. Why is the following situation impossible? The effective force constant of a vibrating HCl molecule is \( k = 480 \text{ N/m} \). A beam of infrared radiation of wavelength 6.20 \times 10^{-6} \text{ nm} is directed through a gas of HCl molecules. As a result, the molecules are excited from the ground vibrational state to the first excited vibrational state.

13. The effective spring constant describing the potential energy of the HI molecule is 320 N/m and that for the HF molecule is 970 N/m. Calculate the minimum amplitude of vibration for (a) the HI molecule and (b) the HF molecule.

14. The rotational spectrum of the HCl molecule contains lines with wavelengths of 0.060 4, 0.069 0, 0.080 4, 0.096 4, and 0.120 4 mm. What is the moment of inertia of the molecule?

15. The atoms of an NaCl molecule are separated by a distance \( r = 0.280 \text{ nm} \). Calculate (a) the reduced mass
of an NaCl molecule, (b) the moment of inertia of an NaCl molecule, and (c) the wavelength of radiation emitted when an NaCl molecule undergoes a transition from the $J = 2$ state to the $J = 1$ state.

16. A diatomic molecule consists of two atoms having masses $m_1$ and $m_2$ separated by a distance $r$. Show that the moment of inertia about an axis through the center of mass of the molecule is given by Equation 43.3, $I = \mu r^2$.

17. The nuclei of the O$_2$ molecule are separated by a distance $1.20 \times 10^{-10}$ m. The mass of each oxygen atom in the molecule is $2.66 \times 10^{-26}$ kg. (a) Determine the rotational energies of an oxygen molecule in electron volts for the levels corresponding to $J = 0$, 1, and 2. (b) The effective force constant $k$ between the atoms in the oxygen molecule is 1.177 N/m. Determine the vibrational energies (in electron volts) corresponding to $v = 0$, 1, and 2.

18. Figure P43.18 is a model of a benzene molecule. All atoms lie in a plane, and the carbon atoms ($m_C = 1.99 \times 10^{-25}$ kg) form a regular hexagon, as do the hydrogen atoms ($m_H = 1.67 \times 10^{-27}$ kg). The carbon atoms are 0.110 nm apart center to center, and the adjacent carbon and hydrogen atoms are 0.100 nm apart center to center. (a) Calculate the moment of inertia of the molecule about an axis perpendicular to the plane of the paper through the center point $O$. (b) Determine the allowed rotational energies about this axis.

19. (a) In an HCl molecule, take the Cl atom to be the isotope $^{35}$Cl. The equilibrium separation of the H and Cl atoms is 0.127 46 nm. The atomic mass of the H atom is 1.007 825 u and that of the $^{35}$Cl atom is 34.968 853 u. Calculate the longest wavelength in the rotational spectrum of this molecule. (b) What If? Repeat the calculation in part (a), but take the Cl atom to be the isotope $^{37}$Cl, which has atomic mass 36.965 903 u. The equilibrium separation distance is the same as in part (a). (c) Naturally occurring chlorine contains approximately three parts of $^{35}$Cl to one part of $^{37}$Cl. Because of the two different Cl masses, each line in the microwave rotational spectrum of HCl is split into a doublet as shown in Figure P43.19. Calculate the separation in wavelength between the doublet lines for the longest wavelength.

20. Estimate the moment of inertia of an HCl molecule from its infrared absorption spectrum shown in Figure P43.19.

21. An H$_2$ molecule is in its vibrational and rotational ground states. It absorbs a photon of wavelength 2.211 2 $\mu$m and makes a transition to the $v = 1, J = 1$ energy level. It then drops to the $v = 0, J = 2$ energy level while emitting a photon of wavelength 2.405 4 $\mu$m. Calculate (a) the moment of inertia of the H$_2$ molecule about an axis through its center of mass and perpendicular to the H–H bond, (b) the vibrational frequency of the H$_2$ molecule, and (c) the equilibrium separation distance for this molecule.

22. Photons of what frequencies can be spontaneously emitted by CO molecules in the state with $v = 1$ and $J = 0$?

23. Most of the mass of an atom is in its nucleus. Model the mass distribution in a diatomic molecule as two spheres of uniform density, each of radius $2.00 \times 10^{-15}$ m and mass $1.00 \times 10^{-20}$ kg, located at points along the y axis as in Figure 43.5a, and separated by $2.00 \times 10^{-10}$ m. Rotation about the axis joining the nuclei in the diatomic molecule is ordinarily ignored because the first excited state would have an energy that is too high to access. To see why, calculate the ratio of the energy of the first excited state for rotation about the $y$ axis to the energy of the first excited state for rotation about the $x$ axis.

24. Use a magnifying glass to look at the grains of table salt that come out of a salt shaker. Compare what you see with Figure 43.11a. The distance between a sodium ion and a nearest-neighbor chlorine ion is 0.261 nm. (a) Make an order-of-magnitude estimate of the number $N$ of atoms in a typical grain of salt. (b) What If? Suppose you had a number of grains of salt equal to this number $N$. What would be the volume of this quantity of salt?

25. Use Equation 43.18 to calculate the ionic cohesive energy for NaCl. Take $\alpha = 1.7476$, $r_0 = 0.281$ nm, and $m = 8$.

26. Consider a one-dimensional chain of alternating singly-ionized positive and negative ions. Show that the
potential energy associated with one of the ions and its interactions with the rest of this hypothetical crystal is

\[ U(r) = -\alpha k \frac{e^2}{r} \]

where the Madelung constant is \( \alpha = 2 \ln 2 \) and \( r \) is the distance between ions. \( \text{Suggestion: Use the series expansion for \( \ln (1 + x) \).} \)

Section 43.4 Free-Electron Theory of Metals

Section 43.5 Band Theory of Solids

27. Calculate the energy of a conduction electron in silver at 800 K, assuming the probability of finding an electron in that state is 0.950. The Fermi energy of silver is 5.48 eV at this temperature.

28. (a) State what the Fermi energy depends on according to the free-electron theory of metals and how the Fermi energy depends on that quantity. (b) Show that Equation 43.25 can be expressed as \( E_r = (3.65 \times 10^{-29}) n_e^{2/3} \), where \( E_r \) is in electron volts when \( n_e \) is in electrons per cubic meter. (c) According to Table 43.2, by what factor does the free-electron concentration in copper exceed that in potassium? (d) Which of these metals has the larger Fermi energy? (e) By what factor is the Fermi energy larger? (f) Explain whether this behavior is predicted by Equation 43.25.

29. When solid silver starts to melt, what is the approximate fraction of the conduction electrons that are thermally excited above the Fermi level?

30. (a) Find the typical speed of a conduction electron in copper, taking its kinetic energy as equal to the Fermi energy, 7.05 eV. (b) Suppose the copper is a current-carrying wire. How does the speed found in part (a) compare with a typical drift speed (see Section 27.1) of electrons in the wire of 0.1 mm/s?

31. The Fermi energy of copper at 300 K is 7.05 eV. (a) What is the average energy of a conduction electron in copper at 300 K? (b) At what temperature would the average translational energy of a molecule in an ideal gas be equal to the energy calculated in part (a)?

32. Consider a cube of gold 1.00 mm on an edge. Calculate the approximate number of conduction electrons in this cube whose energies lie in the range 4.00 to 4.025 eV.

33. Sodium is a monovalent metal having a density of 0.971 g/cm³ and a molar mass of 23.0 g/mol. Use this information to calculate (a) the density of charge carriers and (b) the Fermi energy of sodium.

34. Why is the following situation impossible? A hypothetical metal has the following properties: its Fermi energy is 5.48 eV; its density is 4.90 \( \times 10^3 \) kg/m³; its molar mass is 100 g/mol; and it has one free electron per atom.

35. For copper at 300 K, calculate the probability that a state with an energy equal to 99.0% of the Fermi energy is occupied.

36. For a metal at temperature \( T \), calculate the probability that a state with an energy equal to \( \beta E_r \) is occupied where \( \beta \) is a fraction between 0 and 1.

37. Review. An electron moves in a three-dimensional box of edge length \( L \) and volume \( L^3 \). The wave function of the particle is \( \psi = A \sin (k_x x) \sin (k_y y) \sin (k_z z) \). Show that its energy is given by Equation 43.20,

\[ E = \frac{\hbar^2}{2m} (n_x^2 + n_y^2 + n_z^2) \]

where the quantum numbers \( (n_x, n_y, n_z) \) are integers \( \geq 1 \). \( \text{Suggestion: The Schrödinger equation in three dimensions may be written} \)

\[ \frac{\hbar^2}{2m} \left( \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} \right) = (U - E) \psi \]

38. (a) Consider a system of electrons confined to a three-dimensional box. Calculate the ratio of the number of allowed energy levels at 8.50 eV to the number at 7.05 eV. (b) What If? Copper has a Fermi energy of 7.05 eV at 300 K. Calculate the ratio of the number of occupied levels in copper at an energy of 8.50 eV to the number at the Fermi energy. (c) How does your answer to part (b) compare with that obtained in part (a)?

39. Show that the average kinetic energy of a conduction electron in a metal at 0 K is \( E_{\text{avg}} = \frac{5}{2} E_r \). \( \text{Suggestion: In general, the average kinetic energy is} \)

\[ E_{\text{avg}} = \frac{1}{n_e} \int_0^{E_r} EN(E) dE \]

where \( n_e \) is the density of particles, \( N(E) \ dE \) is given by Equation 43.22, and the integral is over all possible values of the energy.

Section 43.6 Electrical Conduction in Metals, Insulators, and Semiconductors

40. Most solar radiation has a wavelength of 1 \( \mu \text{m} \) or less. (a) What energy gap should the material in a solar cell have if it is to absorb this radiation? (b) Is silicon an appropriate solar cell material (see Table 43.3)? Explain your answer.

41. The energy gap for silicon at 300 K is 1.14 eV. (a) Find the lowest-frequency photon that can promote an electron from the valence band to the conduction band. (b) What is the wavelength of this photon?

42. Light from a hydrogen discharge tube is incident on a CdS crystal. (a) Which spectral lines from the Balmer series are absorbed and (b) which are transmitted?

43. A light-emitting diode (LED) made of the semiconductor GaAsP emits red light (\( \lambda = 650 \text{ nm} \)). Determine the energy-band gap \( E_g \) for this semiconductor.

44. The longest wavelength of radiation absorbed by a certain semiconductor is 0.512 \( \mu \text{m} \). Calculate the energy gap for this semiconductor.

45. You are asked to build a scientific instrument that is thermally isolated from its surroundings. The isolation
container may be a calorimeter, but these design criteria could apply to other containers as well. You wish to use a laser external to the container to raise the temperature of a target inside the instrument. You decide to use a diamond window in the container. Diamond has an energy gap of 5.47 eV. What is the shortest laser wavelength you can use to warm the sample inside the instrument?

46. Review. When a phosphorus atom is substituted for a silicon atom in a crystal, four of the phosphorus valence electrons form bonds with neighboring atoms and the remaining electron is much more loosely bound. You can model the electron as free to move through the crystal lattice. The phosphorus nucleus has one more positive charge than does the silicon nucleus, however, so the extra electron provided by the phosphorus atom is attracted to this single nuclear charge $+e$. The energy levels of the extra electron are similar to those of the electron in the Bohr hydrogen atom with two important exceptions. First, the Coulomb attraction between the electron and the positive charge on the phosphorus nucleus is reduced by a factor of $1/\kappa$ from what it would be in free space (see Eq. 26.21), where $\kappa$ is the dielectric constant of the crystal. As a result, the orbit radii are greatly increased over those of the hydrogen atom. Second, the influence of the periodic electric potential of the lattice causes the electron to move as if it had an effective mass $m^*\kappa$, which is quite different from the mass $m_e$ of a free electron. You can use the Bohr model of hydrogen to obtain relatively accurate values for the allowed energy levels of the extra electron. We wish to find the typical energy of these donor states, which play an important role in semiconductor devices. Assume $\kappa = 11.7$ for silicon and $m^* = 0.220m_e$. (a) Find a symbolic expression for the smallest radius of the electron orbit in terms of $a_0$, the Bohr radius. (b) Substitute numerical values to find the numerical value of the smallest radius. (c) Find a symbolic expression for the energy levels $E_{n\kappa}$ of the electron in the Bohr orbits around the donor atom in terms of $m^*\kappa$, $m_e\kappa$, $K$, and $E_0$, the energy of the hydrogen atom in the Bohr model. (d) Find the numerical value of the energy for the ground state of the electron.

Section 43.7 Semiconductor Devices

47. Assuming $T = 300$ K, (a) for what value of the bias voltage $\Delta V$ in Equation 43.27 does $I = 9.00I_0^\ast$? (b) What if $I = -0.900I_0^\ast$? (c) What if $I = 0$?

48. A diode, a resistor, and a battery are connected in a series circuit. The diode is at a temperature for which $k_BT = 25.0$ meV, and the saturation value of the current is $I_s = 1.00 \mu$A. The resistance of the resistor is $R = 745 \Omega$, and the battery maintains a constant potential difference of $V = 2.42$ V between its terminals. (a) Use Kirchhoff’s loop rule to show that

$$E - \Delta V = I_sR(e^{\Delta V/k_BT} - 1)$$

where $\Delta V$ is the voltage across the diode. (b) To solve this transcendental equation for the voltage $\Delta V$, graph

the left-hand side of the above equation and the right-hand side as functions of $\Delta V$ and find the value of $\Delta V$ at which the curves cross. (c) Find the current $I$ in the circuit. (d) Find the ohmic resistance of the diode, defined as the ratio $\Delta V/I$, at the voltage in part (b). (e) Find the dynamic resistance of the diode, which is defined as the derivative $d(\Delta V)/dI$, at the voltage in part (b).

49. You put a diode in a microelectronic circuit to protect the system in case an untrained person installs the battery backward. In the correct forward-bias situation, the current is 200 mA with a potential difference of 100 mV across the diode at room temperature (300 K). If the battery were reversed, so that the potential difference across the diode is still 100 mV but with the opposite sign, what would be the magnitude of the current in the diode?

50. A diode is at room temperature so that $k_BT = 0.025$ 0 eV. Taking the applied voltages across the diode to be $+1.00$ V (under forward bias) and $-1.00$ V (under reverse bias), calculate the ratio of the forward current to the reverse current if the diode is described by Equation 43.27.

Section 43.8 Superconductivity

Problem 30 in Chapter 30 and Problems 73 through 76 in Chapter 32 can also be assigned with this section.

51. A thin rod of superconducting material 2.50 cm long is placed into a 0.540-T magnetic field with its cylindrical axis along the magnetic field lines. (a) Sketch the directions of the applied field and the induced surface current. (b) Find the magnitude of the surface current on the curved surface of the rod.

52. A direct and relatively simple demonstration of zero DC resistance can be carried out using the four-point probe method. The probe shown in Figure P43.52 consists of a disk of YBa$_2$Cu$_3$O$_7$ (a high-$T_c$ superconductor) to which four wires are attached. Current is maintained through the sample by applying a DC voltage between points $a$ and $b$, and it is measured with a DC ammeter. The current can be varied with the variable resistance $R$. The potential difference $\Delta V_{ad}$ between $c$ and $d$ is measured with a digital voltmeter. When the probe is immersed in liquid nitrogen, the sample quickly cools

Figure P43.52
to 77 K, below the critical temperature of the material, 92 K. The current remains approximately constant, but \( \Delta V_{d} \) drops abruptly to zero. (a) Explain this observation on the basis of what you know about superconductors. (b) The data in the accompanying table represent actual values of \( \Delta V_{d} \) for different values of \( I \) taken on the sample at room temperature in the senior author’s laboratory. A 6-V battery in series with a variable resistor \( R \) supplied the current. The values of \( R \) ranged from 10 \( \Omega \) to 100 \( \Omega \). Make an \( I-\Delta V \) plot of the data and determine whether the sample behaves in a linear manner. (c) From the data, obtain a value for the DC resistance of the sample at room temperature. (d) At room temperature, it was found that \( \Delta V_{d} = 2.234 \text{ mV} \) for \( I = 100.3 \text{ mA} \), but after the sample was cooled to 77 K, \( \Delta V_{d} = 0 \) and \( I = 98.1 \text{ mA} \). What do you think might have caused the slight decrease in current?

### Current Versus Potential Difference \( \Delta V_{d} \), Measured in a Bulk Ceramic Sample of YBa\(_2\)Cu\(_3\)O\(_{7-\delta}\) at Room Temperature

55. A superconducting ring of niobium metal 2.00 cm in diameter is immersed in a uniform 0.020 T magnetic field directed perpendicular to the ring and carries no current. Determine the current generated in the ring when the magnetic field is suddenly decreased to zero. The inductance of the ring is \( 3.10 \times 10^{-8} \text{ H} \).

### Additional Problems

54. The effective spring constant associated with bonding in the \( \text{N}_2 \) molecule is 2.397 N/m. The nitrogen atoms each have a mass of \( 2.32 \times 10^{-26} \text{ kg} \), and their nuclei are 0.120 \( \text{nm} \) apart. Assume the molecule is rigid. The first excited vibrational state of the molecule is above the vibrational ground state by an energy difference \( \Delta E \). Calculate the \( f \)-value of the rotational state that is above the rotational ground state by the same energy difference \( \Delta E \).

55. The hydrogen molecule comes apart (dissociates) when it is excited internally by 4.48 eV. Assuming this molecule behaves like a harmonic oscillator having classical angular frequency \( \omega = 8.28 \times 10^{14} \text{ rad/s} \), find the highest vibrational quantum number for a state below the 4.48-eV dissociation energy.

56. (a) Starting with Equation 43.17, show that the force exerted on an ion in an ionic solid can be written as

\[
F = -ak_{b} \frac{e^{2}}{r^{2}} \left[ 1 - \left( \frac{r_{0}}{r} \right)^{m-1} \right]
\]

where \( a \) is the Madelung constant and \( r_{0} \) is the equilibrium separation. (b) Imagine that an ion in the solid is displaced a small distance \( s \) from \( r_{0} \). Show that the ion experiences a restoring force \( F = -Ks \), where

\[
K = \frac{ak_{b}e^{2}}{r_{0}^{3}} (m - 1)
\]

(c) Use the result of part (b) to find the frequency of vibration of a Na\(^+\) ion in NaCl. Take \( m = 8 \) and use the value \( a = 1.747 \times 10^{-6} \).

57. Under pressure, liquid helium can solidify as each atom bonds with four others, and each bond has an average energy of \( 1.74 \times 10^{-23} \text{ J} \). Find the latent heat of fusion for helium in joules per gram. (The molar mass of He is 4.00 g/mol.)

58. The dissociation energy of ground-state molecular hydrogen is 4.48 eV, but it only takes 3.96 eV to dissociate it when it starts in the first excited vibrational state with \( f = 0 \). Using this information, determine the depth of the H\(_{2}\) molecular potential-energy function.

59. Starting with Equation 43.17, show that the ionic cohesive energy of an ionic bonded solid is given by Equation 43.18.

60. The Fermi–Dirac distribution function can be written as

\[
f(E) = \frac{1}{1 + e^{(E-E_{F})/k_{B}T}}
\]

where \( T_{F} \) is the Fermi temperature, defined according to

\[
k_{b}T_{F} = E_{F}
\]

(a) Write a spreadsheet to calculate and plot \( f(E) \) versus \( E/E_{F} \) at a fixed temperature \( T \). (b) Describe the curves obtained for \( T = 0.1T_{F}, 0.2T_{F}, \) and \( 0.5T_{F} \).

61. A particle moves in one-dimensional motion through a field for which the potential energy of the particle–field system is

\[
U(x) = \frac{A}{x} - \frac{B}{x}
\]

where \( A = 0.150 \text{ eV} \cdot \text{nm}^{3} \) and \( B = 3.68 \text{ eV} \cdot \text{nm} \). The shape of this function is shown in Figure P43.61. (a) Find the equilibrium position \( x_{0} \) of the particle. (b) Determine the depth \( U_{0} \) of this potential well.

![Figure P43.61](attachment:image.png)
(c) In moving along the x axis, what maximum force toward the negative x direction does the particle experience?

62. A particle of mass $m$ moves in one-dimensional motion through a field for which the potential energy of the particle-field system is

$$U(x) = \frac{A}{x^3} - \frac{B}{x}$$

where $A$ and $B$ are constants. The general shape of this function is shown in Figure P43.61. (a) Find the equilibrium position $x_0$ of the particle in terms of $m$, $A$, and $B$. (b) Determine the depth $U_0$ of this potential well. (c) In moving along the x axis, what maximum force toward the negative x direction does the particle experience?

Challenge Problems

63. As you will learn in Chapter 44, carbon-14 ($^{14}$C) is an unstable isotope of carbon. It has the same chemical properties and electronic structure as the much more abundant isotope carbon-12 ($^{12}$C), but it has different nuclear properties. Its mass is 14 u, greater than that of carbon-12 because of the two extra neutrons in the carbon-14 nucleus. Assume the CO molecular potential energy is the same for both isotopes of carbon and the examples in Section 43.2 contain accurate data and results for carbon monoxide with carbon-12 atoms. (a) What is the vibrational frequency of $^{14}$CO? (b) What is the moment of inertia of $^{14}$CO? (c) What wavelengths of light can be absorbed by $^{14}$CO in the ($v = 0, J = 10$) state that cause it to end up in the $v = 1$ state?

64. As an alternative to Equation 43.1, another useful model for the potential energy of a diatomic molecule is the Morse potential

$$U(r) = B[e^{-a(r - r_0)} - 1]^2$$

where $B$, $a$, and $r_0$ are parameters used to adjust the shape of the potential and its depth. (a) What is the equilibrium separation of the nuclei? (b) What is the depth of the potential well, defined as the difference in energy between the potential’s minimum value and its asymptote as $r$ approaches infinity? (c) If $\mu$ is the reduced mass of the system of two nuclei and assuming the potential is nearly parabolic about the well minimum, what is the vibrational frequency of the diatomic molecule in its ground state? (d) What amount of energy needs to be supplied to the ground-state molecule to separate the two nuclei to infinity?
The year 1896 marks the birth of nuclear physics when French physicist Antoine–Henri Becquerel (1852–1908) discovered radioactivity in uranium compounds. This discovery prompted scientists to investigate the details of radioactivity and, ultimately, the structure of the nucleus. Pioneering work by Ernest Rutherford showed that the radiation emitted from radioactive substances is of three types—alpha, beta, and gamma rays—classified according to the nature of their electric charge and their ability to penetrate matter and ionize air. Later experiments showed that alpha rays are helium nuclei, beta rays are electrons, and gamma rays are high-energy photons.

In 1911, Rutherford, Hans Geiger, and Ernest Marsden performed the alpha-particle scattering experiments described in Section 42.2. These experiments established that the nucleus of an atom can be modeled as a point mass and point charge and that most of the atomic mass is contained in the nucleus. Subsequent studies revealed the presence of a new type of force, the short-range nuclear force, which is predominant at particle separation distances less than approximately $10^{-14}$ m and is zero for large distances.

In this chapter, we discuss the properties and structure of the atomic nucleus. We start by describing the basic properties of nuclei, followed by a discussion of nuclear forces and binding energy, nuclear models, and the phenomenon of radioactivity. Finally, we explore the various processes by which nuclei decay and the ways that nuclei can react with each other.
Some Properties of Nuclei

All nuclei are composed of two types of particles: protons and neutrons. The only exception is the ordinary hydrogen nucleus, which is a single proton. We describe the atomic nucleus by the number of protons and neutrons it contains, using the following quantities:

- the atomic number $Z$, which equals the number of protons in the nucleus (sometimes called the charge number)
- the neutron number $N$, which equals the number of neutrons in the nucleus
- the mass number $A = Z + N$, which equals the number of nucleons (neutrons plus protons) in the nucleus

A nuclide is a specific combination of atomic number and mass number that represents a nucleus. In representing nuclides, it is convenient to use the symbol $^AX$ to convey the numbers of protons and neutrons, where $X$ represents the chemical symbol of the element. For example, $^{56}_{26}$Fe (iron) has mass number 56 and atomic number 26; therefore, it contains 26 protons and 30 neutrons. When no confusion is likely to arise, we omit the subscript $Z$ because the chemical symbol can always be used to determine $Z$. Therefore, $^{56}_{26}$Fe is the same as $^{56}$Fe and can also be expressed as “iron-56” or “Fe-56.”

The nuclei of all atoms of a particular element contain the same number of protons but often contain different numbers of neutrons. Nuclei related in this way are called isotopes. The isotopes of an element have the same $Z$ value but different $N$ and $A$ values.

The natural abundance of isotopes can differ substantially. For example, $^{12}$C, $^{13}$C, $^{14}$C, and $^{15}$C are four isotopes of carbon. The natural abundance of the $^{12}$C isotope is approximately 98.9%, whereas that of the $^{13}$C isotope is only about 1.1%. Some isotopes, such as $^{12}$C and $^{15}$C, do not occur naturally but can be produced by nuclear reactions in the laboratory or by cosmic rays.

Even the simplest element, hydrogen, has isotopes: $^1$H, the ordinary hydrogen nucleus; $^2$H, deuterium; and $^3$H, tritium.

Quick Quiz 44.1

For each part of this Quick Quiz, choose from the following answers: (a) protons (b) neutrons (c) nucleons. (i) The three nuclei $^{12}$C, $^{13}$N, and $^{14}$O have the same number of what type of particle? (ii) The three nuclei $^{12}$N, $^{13}$N, and $^{14}$N have the same number of what type of particle? (iii) The three nuclei $^{12}$C, $^{13}$N, and $^{14}$O have the same number of what type of particle?

Charge and Mass

The proton carries a single positive charge $e$, equal in magnitude to the charge $-e$ on the electron ($e = 1.6 \times 10^{-19}$ C). The neutron is electrically neutral as its name implies. Because the neutron has no charge, it was difficult to detect with early experimental apparatus and techniques. Today, neutrons are easily detected with devices such as plastic scintillators.

Nuclear masses can be measured with great precision using a mass spectrometer (see Section 29.3) and by the analysis of nuclear reactions. The proton is approximately 1836 times as massive as the electron, and the masses of the proton and the neutron are almost equal. The atomic mass unit $u$ is defined in such a way that the mass of one atom of the isotope $^{12}$C is exactly 12 u, where 1 u is equal to $1.660539 \times 10^{-27}$ kg. According to this definition, the proton and neutron each have a mass of approximately 1 u and the electron has a mass that is only a small fraction of this value. The masses of these particles and others important to the phenomena discussed in this chapter are given in Table 44.1 (page 1382).
You might wonder how six protons and six neutrons, each having a mass larger than 1 u, can be combined with six electrons to form a carbon-12 atom having a mass of exactly 12 u. The bound system of 12C has a lower rest energy (Section 39.8) than that of six separate protons and six separate neutrons. According to Equation 39.24, \( E_R = mc^2 \), this lower rest energy corresponds to a smaller mass for the bound system. The difference in mass accounts for the binding energy when the particles are combined to form the nucleus. We shall discuss this point in more detail in Section 44.2.

It is often convenient to express the atomic mass unit in terms of its rest-energy equivalent. For one atomic mass unit,

\[
E_R = mc^2 = (1.660539 \times 10^{-27} \text{ kg})(2.99792 \times 10^8 \text{ m/s})^2 = 931.494 \text{ MeV}
\]

where we have used the conversion 1 eV = 1.602176 \times 10^{-19} \text{ J}.

Based on the rest-energy expression in Equation 39.24, nuclear physicists often express mass in terms of the unit MeV/c^2.

**Example 44.1 \ The Atomic Mass Unit**

Use Avogadro’s number to show that 1 u = \( 1.66 \times 10^{-27} \) kg.

**Solution**

**Conceptualize** From the definition of the mole given in Section 19.5, we know that exactly 12 g (= 1 mol) of \(^{12}\text{C} \) contains Avogadro’s number of atoms.

**Categorize** We evaluate the atomic mass unit that was introduced in this section, so we categorize this example as a substitution problem.

Find the mass \( m \) of one \(^{12}\text{C} \) atom:

\[
m = \frac{0.012 \text{ kg}}{6.02 \times 10^{23} \text{ atoms}} = 1.99 \times 10^{-26} \text{ kg}
\]

Because one atom of \(^{12}\text{C} \) is defined to have a mass of 12.0 u, divide by 12.0 to find the mass equivalent to 1 u:

\[
1 \text{ u} = \frac{1.99 \times 10^{-26} \text{ kg}}{12.0} = 1.66 \times 10^{-27} \text{ kg}
\]

**The Size and Structure of Nuclei**

In Rutherford’s scattering experiments, positively charged nuclei of helium atoms (alpha particles) were directed at a thin piece of metallic foil. As the alpha particles moved through the foil, they often passed near a metal nucleus. Because of the positive charge on both the incident particles and the nuclei, the particles were deflected from their straight-line paths by the Coulomb repulsive force.
Rutherford used the isolated system (energy) analysis model to find an expression for the separation distance \( d \) at which an alpha particle approaching a nucleus head-on is turned around by Coulomb repulsion. In such a head-on collision, the mechanical energy of the nucleus-alpha particle system is conserved. The initial kinetic energy of the incoming particle is transformed completely to electric potential energy of the system when the alpha particle stops momentarily at the point of closest approach (the final configuration of the system) before moving back along the same path (Fig. 44.1). Applying Equation 8.2, the conservation of energy principle, to the system gives

\[
\Delta K + \Delta U = 0
\]

\[
(0 - \frac{1}{2} mv^2) + \left( k_e \frac{q_1 q_2}{d} - 0 \right) = 0
\]

where \( m \) is the mass of the alpha particle and \( v \) is its initial speed. Solving for \( d \) gives

\[
d = 2k_e \frac{q_1 q_2}{mv^2} = 2k_e \left( \frac{2e}{mv^2} \right) = 4k_e \frac{Ze^2}{mv^2}
\]

where \( Z \) is the atomic number of the target nucleus. From this expression, Rutherford found that the alpha particles approached nuclei to within \( 3.2 \times 10^{-14} \) m when the foil was made of gold. Therefore, the radius of the gold nucleus must be less than this value. From the results of his scattering experiments, Rutherford concluded that the positive charge in an atom is concentrated in a small sphere, which he called the nucleus, whose radius is no greater than approximately \( 10^{-14} \) m.

Because such small lengths are common in nuclear physics, an often-used convenient length unit is the femtometer (fm), which is sometimes called the fermi and is defined as

\[
1 \text{ fm} = 10^{-15} \text{ m}
\]

In the early 1920s, it was known that the nucleus of an atom contains \( Z \) protons and has a mass nearly equivalent to that of \( A \) protons, where on average \( A \approx 2Z \) for lighter nuclei (\( Z \leq 20 \)) and \( A > 2Z \) for heavier nuclei. To account for the nuclear mass, Rutherford proposed that each nucleus must also contain \( A - Z \) neutral particles that he called neutrons. In 1932, British physicist James Chadwick (1891–1974) discovered the neutron, and he was awarded the Nobel Prize in Physics in 1935 for this important work.

Since the time of Rutherford’s scattering experiments, a multitude of other experiments have shown that most nuclei are approximately spherical and have an average radius given by

\[
r = a A^{1/3}
\]

where \( a \) is a constant equal to \( 1.2 \times 10^{-15} \) m and \( A \) is the mass number. Because the volume of a sphere is proportional to the cube of its radius, it follows from Equation 44.1 that the volume of a nucleus (assumed to be spherical) is directly proportional to \( A \), the total number of nucleons. This proportionality suggests that all nuclei have nearly the same density. When nucleons combine to form a nucleus, they combine as though they were tightly packed spheres (Fig. 44.2). This fact has led to an analogy between the nucleus and a drop of liquid, in which the density of the drop is independent of its size. We shall discuss the liquid-drop model of the nucleus in Section 44.3.

**Example 44.2** **The Volume and Density of a Nucleus**

Consider a nucleus of mass number \( A \).

**(A)** Find an approximate expression for the mass of the nucleus.

continued
Chapter 44  Nuclear Structure

44.2 continued

**Conceptualize** Imagine the nucleus to be a collection of protons and neutrons as shown in Figure 44.2. The mass number \( A \) counts both protons and neutrons.

**Categorize** Let’s assume \( A \) is large enough that we can imagine the nucleus to be spherical.

**Analyze** The mass of the proton is approximately equal to that of the neutron. Therefore, if the mass of one of these particles is \( m \), the mass of the nucleus is approximately \( Am \).

**(B)** Find an expression for the volume of this nucleus in terms of \( A \).

**Solution**

Assume the nucleus is spherical and use Equation 44.1:

\[
V_{\text{nucleus}} = \frac{4}{3} \pi r^3 = \frac{4}{3} \pi a^3 A
\]

**(C)** Find a numerical value for the density of this nucleus.

**Solution**

Use Equation 1.1 and substitute Equation (1):

\[
\rho = \frac{m_{\text{nucleus}}}{V_{\text{nucleus}}} = \frac{Am}{\frac{4}{3} \pi a^3 A} = \frac{3m}{4\pi a^3}
\]

Substitute numerical values:

\[
\rho = \frac{3(1.67 \times 10^{-27} \text{ kg})}{4\pi (1.2 \times 10^{-15} \text{ m})^3} = 2.3 \times 10^{17} \text{ kg/m}^3
\]

**Finalize** The nuclear density is approximately \( 2.3 \times 10^{14} \) times the density of water \( (\rho_{\text{water}} = 1.0 \times 10^3 \text{ kg/m}^3) \).

**What if?** What if the Earth could be compressed until it had this density? How large would it be?

**Answer** Because this density is so large, we predict that an Earth of this density would be very small.

Use Equation 1.1 and the mass of the Earth to find the volume of the compressed Earth:

\[
V = \frac{M_E}{\rho} = \frac{5.97 \times 10^{24} \text{ kg}}{2.3 \times 10^{17} \text{ kg/m}^3} = 2.6 \times 10^7 \text{ m}^3
\]

From this volume, find the radius:

\[
V = \frac{4}{3} \pi r^3 \rightarrow r = \left( \frac{3V}{4\pi} \right)^{1/3} = \left( \frac{3(2.6 \times 10^7 \text{ m}^3)}{4\pi} \right)^{1/3}
\]

\[
r = 1.8 \times 10^2 \text{ m}
\]

An Earth of this radius is indeed a small Earth!

**Nuclear Stability**

You might expect that the very large repulsive Coulomb forces between the close-packed protons in a nucleus should cause the nucleus to fly apart. Because that does not happen, there must be a counteracting attractive force. The nuclear force is a very short range (about 2 fm) attractive force that acts between all nuclear particles. The protons attract each other by means of the nuclear force, and, at the same time, they repel each other through the Coulomb force. The nuclear force also acts between pairs of neutrons and between neutrons and protons. The nuclear force dominates the Coulomb repulsive force within the nucleus (at short ranges), so stable nuclei can exist.

The nuclear force is independent of charge. In other words, the forces associated with the proton–proton, proton–neutron, and neutron–neutron interactions
Some properties of nuclei are the same, apart from the additional repulsive Coulomb force for the proton–proton interaction.

Evidence for the limited range of nuclear forces comes from scattering experiments and from studies of nuclear binding energies. The short range of the nuclear force is shown in the neutron–proton (n–p) potential energy plot of Figure 44.3a obtained by scattering neutrons from a target containing hydrogen. The depth of the n–p potential energy well is 40 to 50 MeV, and there is a strong repulsive component that prevents the nucleons from approaching much closer than 0.4 fm.

The nuclear force does not affect electrons, enabling energetic electrons to serve as point-like probes of nuclei. The charge independence of the nuclear force also means that the main difference between the n–p and p–p interactions is that the p–p potential energy consists of a superposition of nuclear and Coulomb interactions as shown in Figure 44.3b. At distances less than 2 fm, both p–p and n–p potential energies are nearly identical, but for distances of 2 fm or greater, the p–p potential has a positive energy barrier with a maximum at 4 fm.

The existence of the nuclear force results in approximately 270 stable nuclei; hundreds of other nuclei have been observed, but they are unstable. A plot of neutron number $N$ versus atomic number $Z$ for a number of stable nuclei is given in Figure 44.4. The stable nuclei are represented by the black dots, which lie in a narrow range called the line of stability. Notice that the light stable nuclei contain an equal number of protons and neutrons; that is, $N = Z$. Also notice that in heavy stable nuclei, the number of neutrons exceeds the number of protons; above $Z = 20$, the line of stability deviates upward from the line representing $N = Z$. This deviation can be understood by recognizing that as the number of protons increases, the strength of the Coulomb force increases, which tends to break the nucleus apart. As a result, more neutrons are needed to keep the nucleus stable because neutrons experience only the attractive nuclear force. Eventually, the repulsive Coulomb forces between protons cannot be compensated by the addition of more neutrons. This point occurs at $Z = 83$, meaning that elements that contain more than 83 protons do not have stable nuclei.

Figure 44.3 (a) Potential energy versus separation distance for a neutron–proton system.
(b) Potential energy versus separation distance for a proton–proton system. To display the difference in the curves on this scale, the height of the peak for the proton–proton curve has been exaggerated by a factor of 10.

Figure 44.4 Neutron number $N$ versus atomic number $Z$ for stable nuclei (black dots).
44.2 Nuclear Binding Energy

As mentioned in the discussion of $^{12}$C in Section 44.1, the total mass of a nucleus is less than the sum of the masses of its individual nucleons. Therefore, the rest energy of the bound system (the nucleus) is less than the combined rest energy of the separated nucleons. This difference in energy is called the binding energy of the nucleus and can be interpreted as the energy that must be added to a nucleus to break it apart into its components. Therefore, to separate a nucleus into protons and neutrons, energy must be delivered to the system.

Conservation of energy and the Einstein mass–energy equivalence relationship show that the binding energy $E_b$ in MeV of any nucleus is

$$E_b = [Z M(H) + N m_n - M(\frac{A}{2}X)] \times 931.494 \text{ MeV/u}$$

(44.2)

where $M(H)$ is the atomic mass of the neutral hydrogen atom, $m_n$ is the mass of the neutron, $M(\frac{A}{2}X)$ represents the atomic mass of an atom of the isotope $\frac{A}{2}X$, and the masses are all in atomic mass units. The mass of the $Z$ electrons included in $M(H)$ cancels with the mass of the $Z$ electrons included in the term $M(\frac{A}{2}X)$ within a small difference associated with the atomic binding energy of the electrons. Because atomic binding energies are typically several electron volts and nuclear binding energies are several million electron volts, this difference is negligible.

A plot of binding energy per nucleon $E_b/A$ as a function of mass number $A$ for various stable nuclei is shown in Figure 44.5. Notice that the binding energy in Figure 44.5 peaks in the vicinity of $A = 60$. That is, nuclei having mass numbers either greater or less than 60 are not as strongly bound as those near the middle of the periodic table. The decrease in binding energy per nucleon for $A > 60$ implies that energy is released when a heavy nucleus splits, or fissions, into two lighter nuclei. Energy is released in fission because the nucleons in each product nucleus are more tightly bound to one another than are the nucleons in the original nucleus. The important process of fission and a second important process of fusion, in which energy is released as light nuclei combine, shall be considered in detail in Chapter 45.

**Pitfall Prevention 44.2**

**Binding Energy** When separate nucleons are combined to form a nucleus, the energy of the system is reduced. Therefore, the change in energy is negative. The absolute value of this change is called the binding energy. This difference in sign may be confusing. For example, an increase in binding energy corresponds to a decrease in the energy of the system.

![Figure 44.5](https://example.com/figure44.5.png)

**Figure 44.5** Binding energy per nucleon versus mass number for nuclides that lie along the line of stability in Figure 44.4. Some representative nuclides appear as black dots with labels.

The region of greatest binding energy per nucleon is shown by the tan band. Nuclei to the right of $^{208}$Pb are unstable.
Another important feature of Figure 44.5 is that the binding energy per nucleon is approximately constant at around 8 MeV per nucleon for all nuclei with $A > 50$. For these nuclei, the nuclear forces are said to be saturated, meaning that in the closely packed structure shown in Figure 44.2, a particular nucleon can form attractive bonds with only a limited number of other nucleons.

Figure 44.5 provides insight into fundamental questions about the origin of the chemical elements. In the early life of the Universe, the only elements that existed were hydrogen and helium. Clouds of cosmic gas coalesced under gravitational forces to form stars. As a star ages, it produces heavier elements from the lighter elements contained within it, beginning by fusing hydrogen atoms to form helium. This process continues as the star becomes older, generating atoms having larger and larger atomic numbers, up to the tan band shown in Figure 44.5.

The nucleus $^{63}_{28}$Ni has the largest binding energy per nucleon of 8.7945 MeV. It takes additional energy to create elements with mass numbers larger than 63 because of their lower binding energies per nucleon. This energy comes from the supernova explosion that occurs at the end of some large stars’ lives. Therefore, all the heavy atoms in your body were produced from the explosions of ancient stars. You are literally made of stardust!

44.3 Nuclear Models

The details of the nuclear force are still an area of active research. Several nuclear models have been proposed that are useful in understanding general features of nuclear experimental data and the mechanisms responsible for binding energy. Two such models, the liquid-drop model and the shell model, are discussed below.

The Liquid-Drop Model

In 1936, Bohr proposed treating nucleons like molecules in a drop of liquid. In this liquid-drop model, the nucleons interact strongly with one another and undergo frequent collisions as they jiggle around within the nucleus. This jiggling motion is analogous to the thermally agitated motion of molecules in a drop of liquid.

Four major effects influence the binding energy of the nucleus in the liquid-drop model:

- **The volume effect.** Figure 44.5 shows that for $A > 50$, the binding energy per nucleon is approximately constant, which indicates that the nuclear force on a given nucleon is due only to a few nearest neighbors and not to all the other nucleons in the nucleus. On average, then, the binding energy associated with the nuclear force for each nucleon is the same in all nuclei: that associated with an interaction with a few neighbors. This property indicates that the total binding energy of the nucleus is proportional to $A$ and therefore proportional to the nuclear volume. The contribution to the binding energy of the entire nucleus is $C_1A$, where $C_1$ is an adjustable constant that can be determined by fitting the prediction of the model to experimental results.

- **The surface effect.** Because nucleons on the surface of the drop have fewer neighbors than those in the interior, surface nucleons reduce the binding energy by an amount proportional to their number. Because the number of surface nucleons is proportional to the surface area $4\pi r^2$ of the nucleus (modeled as a sphere) and because $r^2 \propto A^{2/3}$ (Eq. 44.1), the surface term can be expressed as $-C_2A^{2/3}$, where $C_2$ is a second adjustable constant.

- **The Coulomb repulsion effect.** Each proton repels every other proton in the nucleus. The corresponding potential energy per pair of interacting protons is $ke^2/r$, where $k_e$ is the Coulomb constant. The total electric potential energy is equivalent to the work required to assemble $Z$ protons, initially infinitely far apart, into a sphere of volume $V$. This energy is proportional to the number
of proton pairs $Z(Z - 1)/2$ and inversely proportional to the nuclear radius. Consequently, the reduction in binding energy that results from the Coulomb effect is $-C_3 Z(Z - 1)/A^{1/3}$, where $C_3$ is yet another adjustable constant.

- **The symmetry effect.** Another effect that lowers the binding energy is related to the symmetry of the nucleus in terms of values of $N$ and $Z$. For small values of $A$, stable nuclei tend to have $N < Z$. Any large asymmetry between $N$ and $Z$ for light nuclei reduces the binding energy and makes the nucleus less stable. For larger $A$, the value of $N$ for stable nuclei is naturally larger than $Z$. This effect can be described by a binding-energy term of the form $-C_4 (N - Z)^2/A$, where $C_4$ is another adjustable constant.\(^1\) For small $A$, any large asymmetry between values of $N$ and $Z$ makes this term relatively large and reduces the binding energy. For large $A$, this term is small and has little effect on the overall binding energy.

Adding these contributions gives the following expression for the total binding energy:

$$E_b = C_1 A - C_2 A^{2/3} - C_3 \frac{Z(Z - 1)}{A^{1/3}} - C_4 \frac{(N - Z)^2}{A} \quad (44.3)$$

This equation, often referred to as the semiempirical binding-energy formula, contains four constants that are adjusted to fit the theoretical expression to experimental data. For nuclei having $A \approx 15$, the constants have the values

- $C_1 = 15.7$ MeV
- $C_2 = 17.8$ MeV
- $C_3 = 0.71$ MeV
- $C_4 = 23.6$ MeV

Equation 44.3, together with these constants, fits the known nuclear mass values very well as shown by the theoretical curve and sample experimental values in Figure 44.6. The liquid-drop model does not, however, account for some finer details of nuclear structure, such as stability rules and angular momentum. Equation 44.3 is a theoretical equation for the binding energy, based on the liquid-drop model, whereas binding energies calculated from Equation 44.2 are experimental values based on mass measurements.

---

**Example 44.3 Applying the Semiempirical Binding–Energy Formula**

The nucleus $^{64}$Zn has a tabulated binding energy of 559.09 MeV. Use the semiempirical binding-energy formula to generate a theoretical estimate of the binding energy for this nucleus.

**Solution**

Imagine bringing the separate protons and neutrons together to form a $^{64}$Zn nucleus. The rest energy of the nucleus is smaller than the rest energy of the individual particles. The difference in rest energy is the binding energy.

From the text of the problem, we know to apply the liquid-drop model. This example is a substitution problem.

For the $^{64}$Zn nucleus, $Z = 30$, $N = 34$, and $A = 64$. Evaluate the four terms of the semiempirical binding-energy formula:

$$C_1 A = (15.7 \text{ MeV})(64) = 1005 \text{ MeV}$$

$$C_2 A^{2/3} = (17.8 \text{ MeV})(64)^{2/3} = 285 \text{ MeV}$$

$$C_3 \frac{Z(Z - 1)}{A^{1/3}} = (0.71 \text{ MeV}) \frac{(30)(29)}{(64)^{1/3}} = 154 \text{ MeV}$$

$$C_4 \frac{(N - Z)^2}{A} = (23.6 \text{ MeV}) \frac{(34 - 30)^2}{64} = 5.90 \text{ MeV}$$

\(^1\)The liquid-drop model describes that heavy nuclei have $N > Z$. The shell model, as we shall see shortly, explains why that is true with a physical argument.
The Shell Model

The liquid-drop model describes the general behavior of nuclear binding energies relatively well. When the binding energies are studied more closely, however, we find the following features:

- Most stable nuclei have an even value of \( A \). Furthermore, only eight stable nuclei have odd values for both \( Z \) and \( N \).
- Figure 44.7 shows a graph of the difference between the binding energy per nucleon calculated by Equation 44.3 and the measured binding energy. There is evidence for regularly spaced peaks in the data that are not described by the semiempirical binding-energy formula. The peaks occur at values of \( N \) or \( Z \) that have become known as magic numbers:
  \[ Z \text{ or } N = 2, 8, 20, 28, 50, 82 \]  
- High-precision studies of nuclear radii show deviations from the simple expression in Equation 44.1. Graphs of experimental data show peaks in the curve of radius versus \( N \) at values of \( N \) equal to the magic numbers.
- A group of isotones is a collection of nuclei having the same value of \( N \) and varying values of \( Z \). When the number of stable isotones is graphed as function of \( N \), there are peaks in the graph, again at the magic numbers in Equation 44.4.
- Several other nuclear measurements show anomalous behavior at the magic numbers.²

These peaks in graphs of experimental data are reminiscent of the peaks in Figure 42.20 for the ionization energy of atoms, which arose because of the shell structure of the atom. The shell model of the nucleus, also called the independent-particle model, was developed independently by two German scientists: Maria Goeppert-Mayer in 1949 and Hans Jensen (1907–1973) in 1950, Goeppert-Mayer and Jensen

shared the 1963 Nobel Prize in Physics for their work. In this model, each nucleon is assumed to exist in a shell, similar to an atomic shell for an electron. The nucleons exist in quantized energy states, and there are few collisions between nucleons. Obviously, the assumptions of this model differ greatly from those made in the liquid-drop model.

The quantized states occupied by the nucleons can be described by a set of quantum numbers. Because both the proton and the neutron have spin \( \frac{1}{2} \), the exclusion principle can be applied to describe the allowed states (as it was for electrons in Chapter 42). That is, each state can contain only two protons (or two neutrons) having opposite spins (Fig. 44.8). The proton states differ from those of the neutrons because the two species move in different potential wells. The proton energy levels are farther apart than the neutron levels because the protons experience a superposition of the Coulomb force and the nuclear force, whereas the neutrons experience only the nuclear force.

One factor influencing the observed characteristics of nuclear ground states is nuclear spin–orbit effects. The atomic spin–orbit interaction between the spin of an electron and its orbital motion in an atom gives rise to the sodium doublet discussed in Section 42.6 and is magnetic in origin. In contrast, the nuclear spin–orbit effect for nucleons is due to the nuclear force. It is much stronger than in the atomic case, and it has opposite sign. When these effects are taken into account, the shell model is able to account for the observed magic numbers.

The shell model helps us understand why nuclei containing an even number of protons and neutrons are more stable than other nuclei. (There are 160 stable even–even isotopes.) Any particular state is filled when it contains two protons (or two neutrons) having opposite spins. An extra proton or neutron can be added to the nucleus only at the expense of increasing the energy of the nucleus. This increase in energy leads to a nucleus that is less stable than the original nucleus. A careful inspection of the stable nuclei shows that the majority have a special stability when their nucleons combine in pairs, which results in a total angular momentum of zero.

The shell model also helps us understand why nuclei tend to have more neutrons than protons. As in Figure 44.8, the proton energy levels are higher than those for neutrons due to the extra energy associated with Coulomb repulsion. This effect becomes more pronounced as \( Z \) increases. Consequently, as \( Z \) increases and higher states are filled, a proton level for a given quantum number will be much higher in energy than the neutron level for the same quantum number. In fact, it will be even higher in energy than neutron levels for higher quantum numbers. Hence, it is more energetically favorable for the nucleus to form with neutrons in the lower energy levels rather than protons in the higher energy levels, so the number of neutrons is greater than the number of protons.

More sophisticated models of the nucleus have been and continue to be developed. For example, the collective model combines features of the liquid-drop and shell models. The development of theoretical models of the nucleus continues to be an active area of research.

### 44.4 Radioactivity

In 1896, Becquerel accidentally discovered that uranyl potassium sulfate crystals emit an invisible radiation that can darken a photographic plate even though the plate is covered to exclude light. After a series of experiments, he concluded that the radiation emitted by the crystals was of a new type, one that requires no external stimulation and was so penetrating that it could darken protected photographic plates and ionize gases. This process of spontaneous emission of radiation by uranium was soon to be called \textbf{radioactivity}.

Subsequent experiments by other scientists showed that other substances were more powerfully radioactive. The most significant early investigations of this type were conducted by Marie and Pierre Curie (1859–1906). After several years of care-
ful and laborious chemical separation processes on tons of pitchblende, a radioac-
tive ore, the Curies reported the discovery of two previously unknown elements, 
both radioactive, named polonium and radium. Additional experiments, including 
Rutherford’s famous work on alpha-particle scattering, suggested that radioactivity 
is the result of the decay, or disintegration, of unstable nuclei.

Three types of radioactive decay occur in radioactive substances: alpha (α) 
decay, in which the emitted particles are $^4\text{He}$ nuclei; beta (β) decay, in which the 
emitted particles are either electrons or positrons; and gamma (γ) decay, in which 
the emitted particles are high-energy photons. A positron is a particle like the elec-
tron in all respects except that the positron has a charge of $+e$. (The positron is the 
antiparticle of the electron; see Section 46.2.) The symbol $e^-$ is used to designate an 
electron, and $e^+$ designates a positron.

We can distinguish among these three forms of radiation by using the scheme 
described in Figure 44.9. The radiation from radioactive samples that emit all three 
types of particles is directed into a region in which there is a magnetic field. Follow-
ning the particle in a field (magnetic) analysis model, the radiation beam splits into 
three components, two bending in opposite directions and the third experiencing 
no change in direction. This simple observation shows that the radiation of the 
undeflected beam carries no charge (the gamma ray), the component deflected 
upward corresponds to positively charged particles (alpha particles), and the com-
ponent deflected downward corresponds to negatively charged particles ($e^-$). If the 
beam includes a positron ($e^+$), it is deflected upward like the alpha particle, but it 
follows a different trajectory due to its smaller mass.

The three types of radiation have quite different penetrating powers. Alpha par-
ticles barely penetrate a sheet of paper, beta particles can penetrate a few millime-
ters of aluminum, and gamma rays can penetrate several centimeters of lead.

The decay process is probabilistic in nature and can be described with statisti-
cal calculations for a radioactive substance of macroscopic size containing a large 
number of radioactive nuclei. For such large numbers, the rate at which a particu-
lar decay process occurs in a sample is proportional to the number of radioactive 
nuclei present (that is, the number of nuclei that have not yet decayed). If $N$ is the 
number of undecayed radioactive nuclei present at some instant, the rate of change 
of $N$ with time is

$$\frac{dN}{dt} = -\lambda N \quad (44.5)$$

where $\lambda$, called the decay constant, is the probability of decay per nucleus per sec-
ond. The negative sign indicates that $dN/dt$ is negative; that is, $N$ decreases in time.

Equation 44.5 can be written in the form

$$\frac{dN}{N} = -\lambda \, dt$$

The charged particles are deflected in opposite directions by the magnetic field, 
and the gamma ray is not deflected at all.

A mixture of sources emits alpha, beta, and gamma rays.

Figure 44.9 The radiation from radioactive sources can be sepa-
rated into three components by using a magnetic field to deflect 
the charged particles. The detector array at the right records the 
events.
which, upon integration, gives

$$N = N_0 e^{-\lambda t}$$  \hfill (44.6)

where the constant $N_0$ represents the number of undecayed radioactive nuclei at $t = 0$. Equation 44.6 shows that the number of undecayed radioactive nuclei in a sample decreases exponentially with time. The plot of $N$ versus $t$ shown in Figure 44.10 illustrates the exponential nature of the decay. The curve is similar to that for the time variation of electric charge on a discharging capacitor in an $RC$ circuit, as studied in Section 28.4.

The decay rate $R$, which is the number of decays per second, can be obtained by combining Equations 44.5 and 44.6:

$$R = \frac{dN}{dt} = \lambda N = \lambda N_0 e^{-\lambda t} = R_0 e^{-\lambda t}$$  \hfill (44.7)

where $R_0 = \lambda N_0$ is the decay rate at $t = 0$. The decay rate $R$ of a sample is often referred to as its activity. Note that both $N$ and $R$ decrease exponentially with time.

Another parameter useful in characterizing nuclear decay is the half-life $T_{1/2}$:

To find an expression for the half-life, we first set $N = N_0/2$ and $t = T_{1/2}$ in Equation 44.6 to give

$$\frac{N_0}{2} = N_0 e^{-\lambda T_{1/2}}$$

Canceling the $N_0$ factors and then taking the reciprocal of both sides, we obtain $e^{\lambda T_{1/2}} = 2$. Taking the natural logarithm of both sides gives

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}$$  \hfill (44.8)

After a time interval equal to one half-life, there are $N_0/2$ radioactive nuclei remaining (by definition); after two half-lives, half of these remaining nuclei have decayed and $N_0/4$ radioactive nuclei are left; after three half-lives, $N_0/8$ are left; and so on. In general, after $n$ half-lives, the number of undecayed radioactive nuclei remaining is

$$N = N_0\left(\frac{1}{2}\right)^n$$  \hfill (44.9)

where $n$ can be an integer or a noninteger.

A frequently used unit of activity is the curie (Ci), defined as

$$1 \text{ Ci} = 3.7 \times 10^{10} \text{ decays/s}$$

This value was originally selected because it is the approximate activity of 1 g of radium. The SI unit of activity is the becquerel (Bq):

$$1 \text{ Bq} = 1 \text{ decay/s}$$

Therefore, $1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$. The curie is a rather large unit, and the more frequently used activity units are the millicurie and the microcurie.
Quick Quiz 44.2 On your birthday, you measure the activity of a sample of $^{210}$Bi, which has a half-life of 5.01 days. The activity you measure is 1.000 μCi. What is the activity of this sample on your next birthday? (a) 1.000 μCi (b) 0 (c) 0.2 μCi (d) ∼ 0.01 μCi (e) ∼ 10$^{-22}$ μCi

Example 44.4 How Many Nuclei Are Left?
The isotope carbon-14, $^{14}$C, is radioactive and has a half-life of 5 730 years. If you start with a sample of 1 000 carbon-14 nuclei, how many nuclei will still be undecayed in 25 000 years?

Solution Conceptualize The time interval of 25 000 years is much longer than the half-life, so only a small fraction of the originally undecayed nuclei will remain.

Categorize The text of the problem allows us to categorize this example as a substitution problem involving radioactive decay.

Analyze Divide the time interval by the half-life to determine the number of half-lives:

$$n = \frac{T}{T/2} = 4.363$$

Determine how many undecayed nuclei are left after this many half-lives using Equation 44.9:

$$N = N_0 \left(\frac{1}{2}\right)^n = 1 000 \left(\frac{1}{2}\right)^{4.363} = 49$$

Finalize As we have mentioned, radioactive decay is a probabilistic process and accurate statistical predictions are possible only with a very large number of atoms. The original sample in this example contains only 1 000 nuclei, which is certainly not a very large number. Therefore, if you counted the number of undecayed nuclei remaining after 25 000 years, it might not be exactly 49.

Example 44.5 The Activity of Carbon
At time $t = 0$, a radioactive sample contains 3.50 μg of pure $^{14}$C, which has a half-life of 20.4 min.

(A) Determine the number $N_0$ of nuclei in the sample at $t = 0$.

Solution Conceptualize The half-life is relatively short, so the number of undecayed nuclei drops rapidly. The molar mass of $^{14}$C is approximately 11.0 g/mol.

Categorize We evaluate results using equations developed in this section, so we categorize this example as a substitution problem.

Find the number of moles in 3.50 μg of pure $^{14}$C:

$$n = \frac{3.50 \times 10^{-6} \text{ g}}{11.0 \text{ g/mol}} = 3.18 \times 10^{-7} \text{ mol}$$

Find the number of undecayed nuclei in this amount of pure $^{14}$C:

$$N_0 = (3.18 \times 10^{-7} \text{ mol})(6.02 \times 10^{23} \text{ nuclei/mol}) = 1.92 \times 10^{17} \text{ nuclei}$$

(B) What is the activity of the sample initially and after 8.00 h?

Solution Find the initial activity of the sample using Equations 44.7 and 44.8:

$$R_0 = \lambda N_0 = \frac{0.693}{T_{1/2}} N_0 = \frac{0.693}{20.4 \text{ min} \left(\frac{1 \text{ min}}{60 \text{ s}}\right)}(1.92 \times 10^{17})$$

$$= (5.66 \times 10^{-4} \text{ s}^{-1})(1.92 \times 10^{17}) = 1.09 \times 10^{14} \text{ Bq}$$

continued
44.5 continued

Use Equation 44.7 to find the activity at
\[ t = 8.00 \text{ h} = 2.88 \times 10^4 \text{ s} \]
\[ R = R_0 e^{-\lambda t} = (1.09 \times 10^{14} \text{ Bq}) e^{-(5.66 \times 10^{-4} \text{ s}^{-1})(2.88 \times 10^4 \text{ s})} = 8.96 \times 10^6 \text{ Bq} \]

Example 44.6 A Radioactive Isotope of Iodine

A sample of the isotope $^{131}$I, which has a half-life of 8.04 days, has an activity of 5.0 mCi at the time of shipment. Upon receipt of the sample at a medical laboratory, the activity is 2.1 mCi. How much time has elapsed between the two measurements?

**Solution**

**Conceptualize** The sample is continuously decaying as it is in transit. The decrease in the activity is 58% during the time interval between shipment and receipt, so we expect the elapsed time to be greater than the half-life of 8.04 d.

**Categorize** The stated activity corresponds to many decays per second, so $N$ is large and we can categorize this problem as one in which we can use our statistical analysis of radioactivity.

**Analyze** Solve Equation 44.7 for the ratio of the final activity to the initial activity:
\[ \frac{R}{R_0} = e^{-\lambda t} \]

Take the natural logarithm of both sides:
\[ \ln \left( \frac{R}{R_0} \right) = -\lambda t \]

Solve for the time $t$:
\[ t = -\frac{1}{\lambda} \ln \left( \frac{R}{R_0} \right) \]

Use Equation 44.8 to substitute for $\lambda$:
\[ t = -\frac{T_{1/2}}{\ln 2} \ln \left( \frac{R}{R_0} \right) \]

Substitute numerical values:
\[ t = -\frac{8.04 \text{ d}}{0.693} \ln \left( \frac{2.1 \text{ mCi}}{5.0 \text{ mCi}} \right) = 10 \text{ d} \]

**Finalize** This result is indeed greater than the half-life, as expected. This example demonstrates the difficulty in shipping radioactive samples with short half-lives. If the shipment is delayed by several days, only a small fraction of the sample might remain upon receipt. This difficulty can be addressed by shipping a combination of isotopes in which the desired isotope is the product of a decay occurring within the sample. It is possible for the desired isotope to be in equilibrium, in which case it is created at the same rate as it decays. Therefore, the amount of the desired isotope remains constant during the shipping process and subsequent storage. When needed, the desired isotope can be separated from the rest of the sample; its decay from the initial activity begins at this point rather than upon shipment.

44.5 The Decay Processes

As we stated in Section 44.4, a radioactive nucleus spontaneously decays by one of three processes: alpha decay, beta decay, or gamma decay. Figure 44.11 shows a close-up view of a portion of Figure 44.4 from $Z = 65$ to $Z = 80$. The black circles are the stable nuclei seen in Figure 44.4. In addition, unstable nuclei above and below the line of stability for each value of $Z$ are shown. Above the line of stability, the blue circles show unstable nuclei that are neutron-rich and undergo a beta decay process in which an electron is emitted. Below the black circles are red circles corresponding to proton-rich unstable nuclei that primarily undergo a beta-decay process in which a positron is emitted or a competing process called electron capture. Beta decay and electron capture are described in more detail below. Further below the line of stabil-
ity (with a few exceptions) are tan circles that represent very proton-rich nuclei for which the primary decay mechanism is alpha decay, which we discuss first.

**Alpha Decay**

A nucleus emitting an alpha particle (\(^4_2\text{He}\)) loses two protons and two neutrons. Therefore, the atomic number \(Z\) decreases by 2, the mass number \(A\) decreases by 4, and the neutron number decreases by 2. The decay can be written

\[
\frac{1}{2}X \rightarrow \frac{1}{2-2}Y + \frac{1}{2}\text{He}
\]

(44.10)

where \(X\) is called the parent nucleus and \(Y\) the daughter nucleus. As a general rule in any decay expression such as this one, (1) the sum of the mass numbers \(A\) must be the same on both sides of the decay and (2) the sum of the atomic numbers \(Z\) must be the same on both sides of the decay. As examples, \(^{238}\text{U}\) and \(^{226}\text{Ra}\) are both alpha emitters and decay according to the schemes

\[
^{238}\text{U} \rightarrow ^{234}\text{Th} + \frac{1}{2}\text{He}
\]

(44.11)

\[
^{226}\text{Ra} \rightarrow ^{222}\text{Rn} + \frac{1}{2}\text{He}
\]

(44.12)

The decay of \(^{226}\text{Ra}\) is shown in Figure 44.12.

When the nucleus of one element changes into the nucleus of another as happens in alpha decay, the process is called spontaneous decay. In any spontaneous decay, relativistic energy and momentum of the parent nucleus as an isolated system must be conserved. The final components of the system are the daughter nucleus and the alpha particle. If we call \(M_X\) the mass of the parent nucleus, \(M_Y\) the mass of the daughter nucleus, and \(M_a\) the mass of the alpha particle, we can define the disintegration energy \(Q\) of the system as

\[
Q = (M_X - M_Y - M_a) c^2
\]

(44.13)

The energy \(Q\) is in joules when the masses are in kilograms and \(c\) is the speed of light, \(3.00 \times 10^8\) m/s. When the masses are expressed in atomic mass units \(u\), however, \(Q\) can be calculated in MeV using the expression

\[
Q = (M_X - M_Y - M_a) \times 931.494\text{ MeV/u}
\]

(44.14)

Table 44.2 (page 1396) contains information on selected isotopes, including masses of neutral atoms that can be used in Equation 44.14 and similar equations.

The disintegration energy \(Q\) is the amount of rest energy transformed and appears in the form of kinetic energy in the daughter nucleus and the alpha particle and is sometimes referred to as the \(Q\) value of the nuclear decay. Consider the case of the \(^{226}\text{Ra}\) decay described in Figure 44.12. If the parent nucleus is at rest before the decay, the total kinetic energy of the products is 4.87 MeV. (See Example 44.7.) Most of this kinetic energy is associated with the alpha particle because this particle is much less massive than the daughter nucleus \(^{222}\text{Rn}\). That is, because the system is also isolated in terms of momentum, the lighter alpha particle recoils with a much higher speed than does the daughter nucleus. Generally, less massive particles carry off most of the energy in nuclear decays.

Experimental observations of alpha-particle energies show a number of discrete energies rather than a single energy because the daughter nucleus may be left in an

---

**Figure 44.11** A close-up view of the line of stability in Figure 44.4 from \(Z = 65\) to \(Z = 80\). The black dots represent stable nuclei as in Figure 44.4. The other colored dots represent unstable isotopes above and below the line of stability, with the color of the dot indicating the primary means of decay.

**Figure 44.12** The alpha decay of radium-226. The radium nucleus is initially at rest. After the decay, the radon nucleus has kinetic energy \(K_{\text{Ra}}\) and momentum \(p_{\text{Ra}}\) and the alpha particle has kinetic energy \(K_a\) and momentum \(p_a\).

excited quantum state after the decay. As a result, not all the disintegration energy is available as kinetic energy of the alpha particle and daughter nucleus. The emission of an alpha particle is followed by one or more gamma-ray photons (discussed shortly) as the excited nucleus decays to the ground state. The observed discrete alpha-particle energies represent evidence of the quantized nature of the nucleus and allow a determination of the energies of the quantum states.

If one assumes $^{238}\text{U}$ (or any other alpha emitter) decays by emitting either a proton or a neutron, the mass of the decay products would exceed that of the parent nucleus, corresponding to a negative $Q$ value. A negative $Q$ value indicates that such a proposed decay does not occur spontaneously.

Quick Quiz

Which of the following is the correct daughter nucleus associated with the alpha decay of $^{157}\text{Hf}$?

- (a) $^{153}\text{Hf}$
- (b) $^{153}\text{Yb}$
- (c) $^{157}\text{Yb}$

Example 44.7

The Energy Liberated When Radium Decays

The $^{226}\text{Ra}$ nucleus undergoes alpha decay according to Equation 44.12.

**A** Calculate the $Q$ value for this process. From Table 44.2, the masses are $226.025410 \text{ u}$ for $^{226}\text{Ra}$, $222.017578 \text{ u}$ for $^{222}\text{Rn}$, and $4.002603 \text{ u}$ for $^{4}\text{He}$.

Conceptualize Study Figure 44.12 to understand the process of alpha decay in this nucleus.

Categorize The parent nucleus is an isolated system that decays into an alpha particle and a daughter nucleus. The system is isolated in terms of both energy and momentum.

Analyze Evaluate $Q$ using Equation 44.14:

$$Q = (M_X - M_Y - M_a) \times 931.494 \text{ MeV/u}$$

$$= (226.025\text{410 u} - 222.017\text{578 u} - 4.002\text{603 u}) \times 931.494 \text{ MeV/u}$$

$$= (0.005\text{229 u}) \times 931.494 \text{ MeV/u} = 4.87 \text{ MeV}$$

**B** What is the kinetic energy of the alpha particle after the decay?

Analyze The value of 4.87 MeV is the disintegration energy for the decay. It includes the kinetic energy of both the alpha particle and the daughter nucleus after the decay. Therefore, the kinetic energy of the alpha particle would be less than 4.87 MeV.

Set up a conservation of momentum equation, noting that the initial momentum of the system is zero:

$$(1) \quad 0 = M_Y v_Y - M_a v_a$$

Set the disintegration energy equal to the sum of the kinetic energies of the alpha particle and the daughter nucleus (assuming the daughter nucleus is left in the ground state):

$$(2) \quad Q = \frac{1}{2} M_a v_a^2 + \frac{1}{2} M_Y v_Y^2$$

Solve Equation (1) for $v_Y$ and substitute into Equation (2):

$$Q = \frac{1}{2} M_a v_a^2 + \frac{1}{2} M_Y \left( \frac{M_a}{M_Y} \right)^2 = \frac{1}{2} M_a v_a^2 \left( 1 + \frac{M_a}{M_Y} \right)$$

Solve for the kinetic energy of the alpha particle:

$$K_a = Q \left( \frac{M_Y}{M_Y + M_a} \right)$$

Evaluate this kinetic energy for the specific decay of $^{226}\text{Ra}$ that we are exploring in this example:

$$K_a = (4.87 \text{ MeV}) \left( \frac{222}{222 + 4} \right) = 4.78 \text{ MeV}$$

Finalize The kinetic energy of the alpha particle is indeed less than the disintegration energy, but notice that the alpha particle carries away most of the energy available in the decay.
To understand the mechanism of alpha decay, let’s model the parent nucleus as a system consisting of (1) the alpha particle, already formed as an entity within the nucleus, and (2) the daughter nucleus that will result when the alpha particle is emitted. Figure 44.13 shows a plot of potential energy versus separation distance $r$ between the alpha particle and the daughter nucleus, where the distance marked $R$ is the range of the nuclear force. The curve represents the combined effects of (1) the repulsive Coulomb force, which gives the positive part of the curve for $r > R$, and (2) the attractive nuclear force, which causes the curve to be negative for $r < R$. As shown in Example 44.7, a typical disintegration energy $Q$ is approximately 5 MeV, which is the approximate kinetic energy of the alpha particle, represented by the lower dashed line in Figure 44.13.

According to classical physics, the alpha particle is trapped in a potential well. How, then, does it ever escape from the nucleus? The answer to this question was first provided by George Gamow (1904–1968) in 1928 and independently by R. W. Gurney (1898–1953) and E. U. Condon (1902–1974) in 1929, using quantum mechanics. In the view of quantum mechanics, there is always some probability that a particle can tunnel through a barrier (Section 41.5). That is exactly how we can describe alpha decay: the alpha particle tunnels through the barrier in Figure 44.13, escaping the nucleus. Furthermore, this model agrees with the observation that higher-energy alpha particles come from nuclei with shorter half-lives. For higher-energy alpha particles in Figure 44.13, the barrier is narrower and the probability is higher that tunneling occurs. The higher probability translates to a shorter half-life.

As an example, consider the decays of $^{238}\text{U}$ and $^{226}\text{Ra}$ in Equations 44.11 and 44.12, along with the corresponding half-lives and alpha-particle energies:

\[
^{238}\text{U}: \quad T_{1/2} = 4.47 \times 10^9 \text{ yr} \quad K_a = 4.20 \text{ MeV}
\]

\[
^{226}\text{Ra}: \quad T_{1/2} = 1.60 \times 10^5 \text{ yr} \quad K_a = 4.78 \text{ MeV}
\]

Notice that a relatively small difference in alpha-particle energy is associated with a tremendous difference of six orders of magnitude in the half-life. The origin of this effect can be understood as follows. Figure 44.13 shows that the curve below an alpha-particle energy of 5 MeV has a slope with a relatively small magnitude. Therefore, a small difference in energy on the vertical axis has a relatively large effect on the width of the potential barrier. Second, recall Equation 41.22, which describes the exponential dependence of the probability of transmission on the barrier width. These two factors combine to give the very sensitive relationship between half-life and alpha-particle energy that the data above suggest.

A life-saving application of alpha decay is the household smoke detector, shown in Figure 44.14. The detector consists of an ionization chamber, a sensitive current detector, and an alarm. A weak radioactive source (usually $^{241}\text{Am}$) ionizes the air in the chamber of the detector, creating charged particles. A voltage is maintained between the plates inside the chamber, setting up a small but detectable current in the external circuit due to the ions acting as charge carriers between the plates. As long as the current is maintained, the alarm is deactivated. If smoke drifts into the chamber, however, the ions become attached to the smoke particles. These heavier particles do not drift as readily as do the lighter ions, which causes a decrease in the detector current. The external circuit senses this decrease in current and sets off the alarm.

**Beta Decay**

When a radioactive nucleus undergoes beta decay, the daughter nucleus contains the same number of nucleons as the parent nucleus but the atomic number is changed by 1, which means that the number of protons changes:

\[
^{A}_Z\text{X} \rightarrow ^{A}_{Z+1}\text{Y} + e^- \quad \text{(incomplete expression)} \tag{44.15}
\]

\[
^{A}_Z\text{X} \rightarrow ^{A}_{Z-1}\text{Y} + e^+ \quad \text{(incomplete expression)} \tag{44.16}
\]
where, as mentioned in Section 44.4, \( e^- \) designates an electron and \( e^+ \) designates a positron, with beta particle being the general term referring to either. Beta decay is not described completely by these expressions. We shall give reasons for this statement shortly.

As with alpha decay, the nucleon number and total charge are both conserved in beta decays. Because \( A \) does not change but \( Z \) does, we conclude that in beta decay, either a neutron changes to a proton (Eq. 44.15) or a proton changes to a neutron (Eq. 44.16). Note that the electron or positron emitted in these decays is not present beforehand in the nucleus; it is created in the process of the decay from the rest energy of the decaying nucleus. Two typical beta-decay processes are

\[
\begin{align*}
^{14}_{6}\text{C} & \rightarrow ^{14}_{7}\text{N} + e^- \quad (\text{incomplete expression}) \quad (44.17) \\
^{12}_{7}\text{N} & \rightarrow ^{12}_{6}\text{C} + e^+ \quad (\text{incomplete expression}) \quad (44.18)
\end{align*}
\]

Let’s consider the energy of the system undergoing beta decay before and after the decay. As with alpha decay, energy of the isolated system must be conserved. Experimentally, it is found that beta particles from a single type of nucleus are emitted over a continuous range of energies (Fig. 44.15a), as opposed to alpha decay, in which the alpha particles are emitted with discrete energies (Fig. 44.15b). The kinetic energy of the system after the decay is equal to the decrease in rest energy of the system, that is, the \( Q \) value. Because all decaying nuclei in the sample have the same initial mass, however, the \( Q \) value must be the same for each decay.

So, why do the emitted particles have the range of kinetic energies shown in Figure 44.15a? The isolated system model and the law of conservation of energy seem to be violated! It becomes worse: further analysis of the decay processes described by Equations 44.15 and 44.16 shows that the laws of conservation of angular momentum (spin) and linear momentum are also violated!

After a great deal of experimental and theoretical study, Pauli in 1930 proposed that a third particle must be present in the decay products to carry away the “missing” energy and momentum. Fermi later named this particle the neutrino (little neutral one) because it had to be electrically neutral and have little or no mass. Although it eluded detection for many years, the neutrino (symbol \( \nu \), Greek nu) was finally detected experimentally in 1956 by Frederick Reines (1918–1998), who received the Nobel Prize in Physics for this work in 1995. The neutrino has the following properties:

- It has zero electric charge.
- Its mass is either zero (in which case it travels at the speed of light) or very small; much recent persuasive experimental evidence suggests that the neutrino mass is not zero. Current experiments place the upper bound of the mass of the neutrino at approximately 7 eV/c^2.
- It has a spin of \( \frac{1}{2} \), which allows the law of conservation of angular momentum to be satisfied in beta decay.
- It interacts very weakly with matter and is therefore very difficult to detect.

We can now write the beta-decay processes (Eqs. 44.15 and 44.16) in their correct and complete form:

\[
\begin{align*}
^{A}_{Z}\text{X} & \rightarrow ^{A}_{Z+1}\text{Y} + e^- + \bar{\nu} \quad (\text{complete expression}) \quad (44.19) \\
^{A}_{Z}\text{X} & \rightarrow ^{A}_{Z-1}\text{Y} + e^+ + \nu \quad (\text{complete expression}) \quad (44.20)
\end{align*}
\]

as well as those for carbon-14 and nitrogen-12 (Eqs. 44.17 and 44.18):

\[
\begin{align*}
^{14}_{6}\text{C} & \rightarrow ^{14}_{7}\text{N} + e^- + \bar{\nu} \quad (\text{complete expression}) \quad (44.21) \\
^{12}_{7}\text{N} & \rightarrow ^{12}_{6}\text{C} + e^+ + \nu \quad (\text{complete expression}) \quad (44.22)
\end{align*}
\]

where the symbol \( \bar{\nu} \) represents the antineutrino, the antiparticle to the neutrino. We shall discuss antiparticles further in Chapter 46. For now, it suffices to say that a neutrino is emitted in positron decay and an antineutrino is emitted in electron
As with alpha decay, the decays listed above are analyzed by applying conservation laws, but relativistic expressions must be used for beta particles because their kinetic energy is large (typically 1 MeV) compared with their rest energy of 0.511 MeV. Figure 44.16 shows a pictorial representation of the decays described by Equations 44.21 and 44.22.

In Equation 44.19, the number of protons has increased by one and the number of neutrons has decreased by one. We can write the fundamental process of e⁻ decay in terms of a neutron changing into a proton as follows:

$$n \rightarrow p + e^- + \bar{\nu} \quad (44.23)$$

The electron and the antineutrino are ejected from the nucleus, with the net result that there is one more proton and one fewer neutron, consistent with the changes in $Z$ and $A - Z$. A similar process occurs in e⁺ decay, with a proton changing into a neutron, a positron, and a neutrino. This latter process can only occur within the nucleus, with the result that the nuclear mass decreases. It cannot occur for an isolated proton because its mass is less than that of the neutron.

A process that competes with e⁺ decay is electron capture, which occurs when a parent nucleus captures one of its own orbital electrons and emits a neutrino. The final product after decay is a nucleus whose charge is $Z - 1$:

$$\frac{2}{3}X + \frac{2}{3}e^- \rightarrow Z-1Y + \nu \quad (44.24)$$

In most cases, it is a K-shell electron that is captured and the process is therefore referred to as K capture. One example is the capture of an electron by \(^7\)Be:

$$\frac{2}{3}Be + \frac{2}{3}e^- \rightarrow \frac{2}{3}Li + \nu$$

Because the neutrino is very difficult to detect, electron capture is usually observed by the x-rays given off as higher-shell electrons cascade downward to fill the vacancy created in the K shell.

Finally, we specify $Q$ values for the beta-decay processes. The $Q$ values for e⁻ decay and electron capture are given by $Q = (M_X - M_Y)c^2$, where $M_X$ and $M_Y$ are the masses of neutral atoms. In e⁻ decay, the parent nucleus experiences an increase in atomic number and, for the atom to become neutral, an electron must be absorbed by the atom. If the neutral parent atom and an electron (which will eventually combine with the daughter to form a neutral atom) is the initial system and the final system is the neutral daughter atom and the beta-ejected electron, the system contains a free electron both before and after the decay. Therefore, in subtracting the initial and final masses of the system, this electron mass cancels.

---

**Figure 44.16** (a) The beta decay of carbon-14. (b) The beta decay of nitrogen-12.

---

**Pitfall Prevention 44.7**

**Mass Number of the Electron** An alternative notation for an electron, as we see in Equation 44.24, is the symbol \(\frac{2}{3}e\), which does not imply that the electron has zero rest energy. The mass of the electron is so much smaller than that of the lightest nucleon, however, that we approximate it as zero in the context of nuclear decays and reactions.
The $Q$ values for $e^+$ decay are given by $Q = (M_X - M_Y - 2m_e)c^2$. The extra term $-2m_e c^2$ in this expression is necessary because the atomic number of the parent decreases by one when the daughter is formed. After it is formed by the decay, the daughter atom sheds one electron to form a neutral atom. Therefore, the final products are the daughter atom, the shed electron, and the ejected positron.

These relationships are useful in determining whether or not a process is energetically possible. For example, the $Q$ value for proposed $e^+$ decay for a particular parent nucleus may turn out to be negative. In that case, this decay does not occur. The $Q$ value for electron capture for this parent nucleus, however, may be a positive number, so electron capture can occur even though $e^+$ decay is not possible. Such is the case for the decay of $\beta^5$Be shown above.

Quick Quiz 44.4 Which of the following is the correct daughter nucleus associated with the beta decay of $^{184}_{72}$Hf? (a) $^{183}_{72}$Hf (b) $^{183}_{73}$Ta (c) $^{184}_{73}$Ta

Carbon Dating

The beta decay of $^{14}$C (Eq. 44.21) is commonly used to date organic samples. Cosmic rays in the upper atmosphere cause nuclear reactions (Section 44.7) that create $^{14}$C. The ratio of $^{14}$C to $^{12}$C in the carbon dioxide molecules of our atmosphere has a constant value of approximately $r_0 = 1.3 \times 10^{-12}$. The carbon atoms in all living organisms have this same $^{14}$C/$^{12}$C ratio $r_0$ because the organisms continuously exchange carbon dioxide with their surroundings. When an organism dies, however, it no longer absorbs $^{14}$C from the atmosphere, and so the $^{14}$C/$^{12}$C ratio decreases as the $^{14}$C decays with a half-life of 5 730 yr. It is therefore possible to measure the age of a material by measuring its $^{14}$C activity. Using this technique, scientists have been able to identify samples of wood, charcoal, bone, and shell as having lived from 1 000 to 25 000 years ago. This knowledge has helped us reconstruct the history of living organisms—including humans—during this time span.

A particularly interesting example is the dating of the Dead Sea Scrolls. This group of manuscripts was discovered by a shepherd in 1947. Translation showed them to be religious documents, including most of the books of the Old Testament. Because of their historical and religious significance, scholars wanted to know their age. Carbon dating applied to the material in which they were wrapped established their age at approximately 1 950 yr.

Conceptual Example 44.8 The Age of Iceman

In 1991, German tourists discovered the well-preserved remains of a man, now called “Ötzi the Iceman,” trapped in a glacier in the Italian Alps. (See the photograph at the opening of this chapter.) Radioactive dating with $^{14}$C revealed that this person was alive approximately 5 300 years ago. Why did scientists date a sample of Ötzi using $^{14}$C rather than $^{11}$C, which is a beta emitter having a half-life of 20.4 min?

Solution

Because $^{14}$C has a half-life of 5 730 yr, the fraction of $^{14}$C nuclei remaining after thousands of years is high enough to allow accurate measurements of changes in the sample’s activity. Because $^{11}$C has a very short half-life, it is not useful; its activity decreases to a vanishingly small value over the age of the sample, making it impossible to detect.

An isotope used to date a sample must be present in a known amount in the sample when it is formed. As a general rule, the isotope chosen to date a sample should also have a half-life that is on the same order of magnitude as the age of the sample. If the half-life is much less than the age of the sample, there won’t be enough activity left to measure because almost all the original radioactive nuclei will have decayed. If the half-life is much greater than the age of the sample, the amount of decay that has taken place since the sample died will be too small to measure. For example, if you have a specimen estimated...
to have died 50 years ago, neither $^{14}$C (5730 yr) nor $^{11}$C (20 min) is suitable. If you know your sample contains hydrogen, however, you can measure the activity of $^{3}$H (tritium), a beta emitter that has a half-life of 12.3 yr.

---

### Example 44.9 Radioactive Dating

A piece of charcoal containing 25.0 g of carbon is found in some ruins of an ancient city. The sample shows a $^{14}$C activity $R$ of 250 decays/min. How long has the tree from which this charcoal came been dead?

**Solution**

**Conceptualize** Because the charcoal was found in ancient ruins, we expect the current activity to be smaller than the initial activity. If we can determine the initial activity, we can find out how long the wood has been dead.

**Categorize** The text of the question helps us categorize this example as a carbon dating problem.

**Analyze** Solve Equation 44.7 for $t$:

\[
(1) \quad t = -\frac{1}{\lambda} \ln \left( \frac{R}{R_0} \right)
\]

Evaluate the ratio $R/R_0$ using Equation 44.7, the initial value of the $^{14}$C/$^{12}$C ratio $r_0$, the number of moles $n$ of carbon, and Avogadro’s number $N_A$:

\[
\frac{R}{R_0} = \frac{R}{\lambda N_0 (14C)} = \frac{R}{\lambda r_0 N_0 (12C)} = \frac{R}{\lambda r_0 n N_A}
\]

Replace the number of moles in terms of the molar mass $M$ of carbon and the mass $m$ of the sample and substitute for the decay constant $\lambda$:

\[
\frac{R}{R_0} = \frac{R}{(\ln 2/T_{1/2}) r_0 (m/M) N_A} = \frac{RMT_{1/2}}{r_0 m N_A \ln 2}
\]

Substitute numerical values:

\[
\frac{R}{R_0} = \frac{(250 \text{ min}^{-1})(12.0 \text{ g/mol})(5730 \text{ yr})}{(1.3 \times 10^{-12})(25.0 \text{ g})(6.022 \times 10^{23} \text{ mol}^{-1}) \ln 2} = 0.667
\]

Substitute this ratio into Equation (1) and substitute for the decay constant $\lambda$:

\[
t = -\frac{1}{\lambda} \ln \left( \frac{R}{R_0} \right) = -\frac{T_{1/2}}{\ln 2} \ln \left( \frac{R}{R_0} \right)
\]

\[
= -\frac{5730 \text{ yr}}{\ln 2} \ln (0.667) = 3.4 \times 10^{3} \text{ yr}
\]

**Finalize** Note that the time interval found here is on the same order of magnitude as the half-life, so $^{14}$C is a valid isotope to use for this sample, as discussed in Conceptual Example 44.8.

---

### Gamma Decay

Very often, a nucleus that undergoes radioactive decay is left in an excited energy state. The nucleus can then undergo a second decay to a lower-energy state, perhaps to the ground state, by emitting a high-energy photon:

\[
\frac{3}{2}X^* \rightarrow \frac{3}{2}X + \gamma \quad (44.25)
\]

where $X^*$ indicates a nucleus in an excited state. The typical half-life of an excited nuclear state is $10^{-10}$ s. Photons emitted in such a de-excitation process are called gamma rays. Such photons have very high energy (1 MeV to 1 GeV) relative to the energy of visible light (approximately 1 eV). Recall from Section 42.3 that the energy of a photon emitted or absorbed by an atom equals the difference in energy
between the two electronic states involved in the transition. Similarly, a gamma-ray photon has an energy $\Delta E$ that equals the energy difference $\Delta E$ between two nuclear energy levels. When a nucleus decays by emitting a gamma ray, the only change in the nucleus is that it ends up in a lower-energy state. There are no changes in $Z$, $N$, or $A$.

A nucleus may reach an excited state as the result of a violent collision with another particle. More common, however, is for a nucleus to be in an excited state after it has undergone alpha or beta decay. The following sequence of events represents a typical situation in which gamma decay occurs:

$$^{12}_6B \rightarrow ^{12}_6C^* + e^- + \bar{\nu} \quad (44.26)$$
$$^{12}_6C^* \rightarrow ^{12}_6C + \gamma \quad (44.27)$$

Figure 44.17 shows the decay scheme for $^{12}_6B$, which undergoes beta decay to either of two levels of $^{12}_6C$. It can either (1) decay directly to the ground state of $^{12}_6C$ by emitting a 13.4-MeV electron or (2) undergo beta decay to an excited state of $^{12}_6C^*$ followed by gamma decay to the ground state. The latter process results in the emission of a 9.0-MeV electron and a 4.4-MeV photon.

The various pathways by which a radioactive nucleus can undergo decay are summarized in Table 44.3.

### Natural Radioactivity

Radioactive nuclei are generally classified into two groups: (1) unstable nuclei found in nature, which give rise to natural radioactivity, and (2) unstable nuclei produced in the laboratory through nuclear reactions, which exhibit artificial radioactivity.

As Table 44.4 shows, there are three series of naturally occurring radioactive nuclei. Each series starts with a specific long-lived radioactive isotope whose half-life exceeds that of any of its unstable descendants. The three natural series begin with the isotopes $^{238}_{92}U$, $^{235}_{92}U$, and $^{232}_{90}Th$, and the corresponding stable end products are three isotopes of lead: $^{206}_{82}Pb$, $^{207}_{82}Pb$, and $^{208}_{82}Pb$. The fourth series in Table 44.4 begins with $^{237}_{93}Np$ and has as its stable end product $^{209}_{82}Bi$. The element $^{237}_{93}Np$ is a transuranic element (one having an atomic number greater than that of uranium) not found in nature. This element has a half-life of “only” $2.14 \times 10^6$ years.

Figure 44.18 shows the successive decays for the $^{235}_{92}Th$ series. First, $^{235}_{92}Th$ undergoes alpha decay to $^{229}_{86}Ra$. Next, $^{229}_{86}Ra$ undergoes two successive beta decays to $^{229}_{82}Th$. The series continues and finally branches when it reaches $^{212}_{82}Bi$. At this point, there are two decay possibilities. The sequence shown in Figure 44.18 is characterized by a mass-number decrease of either 4 (for alpha decays) or 0 (for beta or gamma decays). The two uranium series are more complex than the $^{232}_{90}Th$ series. In addition, several naturally occurring radioactive isotopes, such as $^{14}_{6}C$ and $^{40}_{17}K$, are not part of any decay series.

Because of these radioactive series, our environment is constantly replenished with radioactive elements that would otherwise have disappeared long ago. For example, because our solar system is approximately $5 \times 10^9$ years old, the supply of...
$^{226}$Ra (whose half-life is only 1,600 years) would have been depleted by radioactive decay long ago if it were not for the radioactive series starting with $^{238}$U.

### 44.7 Nuclear Reactions

We have studied radioactivity, which is a spontaneous process in which the structure of a nucleus changes. It is also possible to stimulate changes in the structure of nuclei by bombarding them with energetic particles. Such collisions, which change the identity of the target nuclei, are called nuclear reactions. Rutherford was the first to observe them, in 1919, using naturally occurring radioactive sources for the bombarding particles. Since then, a wide variety of nuclear reactions has been observed following the development of charged-particle accelerators in the 1930s. With today’s advanced technology in particle accelerators and particle detectors, the Large Hadron Collider (see Section 46.10) in Europe can achieve particle energies of 14,000 GeV = 14 TeV. These high-energy particles are used to create new particles whose properties are helping to solve the mysteries of the nucleus.

Consider a reaction in which a target nucleus $X$ is bombarded by a particle $a$, resulting in a daughter nucleus $Y$ and an outgoing particle $b$:

$$ a + X \rightarrow Y + b $$

Sometimes this reaction is written in the more compact form

$$ X(a, b)Y $$

In Section 44.5, the $Q$ value, or disintegration energy, of a radioactive decay was defined as the rest energy transformed to kinetic energy as a result of the decay process. Likewise, we define the reaction energy $Q$ associated with a nuclear reaction as the difference between the initial and final rest energies resulting from the reaction:

$$ Q = (M_a + M_X - M_Y - M_b)c^2 $$

As an example, consider the reaction $^7$Li$(p, a)^4$He. The notation $p$ indicates a proton, which is a hydrogen nucleus. Therefore, we can write this reaction in the expanded form

$$ ^1H + ^3$Li \rightarrow ^4$He + $^2$He

The $Q$ value for this reaction is 17.3 MeV. A reaction such as this one, for which $Q$ is positive, is called exothermic. A reaction for which $Q$ is negative is called endothermic. To satisfy conservation of momentum for the isolated system, an endothermic reaction does not occur unless the bombarding particle has a kinetic energy greater than $Q$. (See Problem 74.) The minimum energy necessary for such a reaction to occur is called the threshold energy.

If particles $a$ and $b$ in a nuclear reaction are identical so that $X$ and $Y$ are also necessarily identical, the reaction is called a scattering event. If the kinetic energy of the system ($a$ and $X$) before the event is the same as that of the system ($b$ and $Y$) after the event, it is classified as elastic scattering. If the kinetic energy of the system after the event is less than that before the event, the reaction is described as inelastic scattering. In this case, the target nucleus has been raised to an excited state by the event, which accounts for the difference in energy. The final system now consists of $b$ and an excited nucleus $Y^*$, and eventually it will become $b$, $Y$, and $\gamma$, where $\gamma$ is the gamma-ray photon that is emitted when the system returns to the ground state. This elastic and inelastic terminology is identical to that used in describing collisions between macroscopic objects as discussed in Section 9.4.

In addition to energy and momentum, the total charge and total number of nucleons must be conserved in any nuclear reaction. For example, consider the
reaction $^{19}\text{F}(p, \alpha)^{16}\text{O}$, which has a $Q$ value of 8.11 MeV. We can show this reaction more completely as

$$^1\text{H} + ^{19}\text{F} \rightarrow ^{16}\text{O} + ^2\text{He} \quad (44.30)$$

The total number of nucleons before the reaction (1 + 19 = 20) is equal to the total number after the reaction (16 + 4 = 20). Furthermore, the total charge is the same before (1 + 9) and after (8 + 2) the reaction.

### 44.8 Nuclear Magnetic Resonance and Magnetic Resonance Imaging

In this section, we describe an important application of nuclear physics in medicine called magnetic resonance imaging. To understand this application, we first discuss the spin angular momentum of the nucleus. This discussion has parallels with the discussion of spin for atomic electrons.

In Chapter 42, we discussed that the electron has an intrinsic angular momentum, called spin. Nuclei also have spin because their component particles—neutrons and protons—each have spin $\frac{1}{2}$ as well as orbital angular momentum within the nucleus. All types of angular momentum obey the quantum rules that were outlined for orbital and spin angular momentum in Chapter 42. In particular, two quantum numbers associated with the angular momentum determine the allowed values of the magnitude of the angular momentum vector and its direction in space. The magnitude of the nuclear angular momentum is $I \hbar$, where $I$ is the nuclear spin quantum number and may be an integer or a half-integer, depending on how the individual proton and neutron spins combine. The quantum number $I$ is the analog to $l$ for the electron in a atom as discussed in Section 42.6. Furthermore, there is a quantum number $m_I$ that is the analog to $m$, in that the allowed projections of the nuclear spin angular momentum vector along the $z$ axis are $m_I \hbar$. The values of $m_I$ range from $-I$ to $+I$ in steps of 1. (In fact, for any type of spin with a quantum number $S$, there is a quantum number $m_S$ that ranges in value from $-S$ to $+S$ in steps of 1.) Therefore, the maximum value of the $z$ component of the spin angular momentum vector is $I \hbar$. Figure 44.19 is a vector model (see Section 42.6) illustrating the possible orientations of the nuclear spin vector and its projections along the $z$ axis for the case in which $I = \frac{3}{2}$.

Nuclear spin has an associated nuclear magnetic moment, similar to that of the electron. The spin magnetic moment of a nucleus is measured in terms of the nuclear magneton $\mu_n$, a unit of moment defined as

$$\mu_n = \frac{e \hbar}{2m_p} = 5.05 \times 10^{-27} \text{ J/T} \quad (44.31)$$

where $m_p$ is the mass of the proton. This definition is analogous to that of the Bohr magneton $\mu_B$, which corresponds to the spin magnetic moment of a free electron (see Section 42.6). Note that $\mu_n$ is smaller than $\mu_B (= 9.274 \times 10^{-24} \text{ J/T})$ by a factor of 1,836 because of the large difference between the proton mass and the electron mass.

The magnetic moment of a free proton is $2.792 \mu_n$. Unfortunately, there is no general theory of nuclear magnetism that explains this value. The neutron also has a magnetic moment, which has a value of $-1.913 \mu_n$. The negative sign indicates that this moment is opposite the spin angular momentum of the neutron. The existence of a magnetic moment for the neutron is surprising in view of the neutron being uncharged. That suggests that the neutron is not a fundamental particle but rather has an underlying structure consisting of charged constituents. We shall explore this structure in Chapter 46.
Nuclear Magnetic Resonance and Magnetic Resonance Imaging

The potential energy associated with a magnetic dipole moment $\mu_S$ in an external magnetic field $B_S$ is given by $\Delta E = \mu_S \cdot B_S$ (Eq. 29.18). When the magnetic moment $\mu_S$ is lined up with the field as closely as quantum physics allows, the potential energy of the dipole–field system has its minimum value $E_{\text{min}}$. When $\mu_S$ is as antiparallel to the field as possible, the potential energy has its maximum value $E_{\text{max}}$. In general, there are other energy states between these values corresponding to the quantized directions of the magnetic moment with respect to the field. For a nucleus with spin $\frac{1}{2}$, there are only two allowed states, with energies $E_{\text{min}}$ and $E_{\text{max}}$. These two energy states are shown in Figure 44.20.

It is possible to observe transitions between these two spin states using a technique called NMR, for nuclear magnetic resonance. A constant magnetic field ($B_S$ in Fig. 44.20) is introduced to define a $z$ axis and split the energies of the spin states. A second, weaker, oscillating magnetic field is then applied perpendicular to $B_S$, creating a cloud of radio-frequency photons around the sample. When the frequency of the oscillating field is adjusted so that the photon energy matches the energy difference between the spin states, there is a net absorption of photons by the nuclei that can be detected electronically.

Figure 44.21 is a simplified diagram of the apparatus used in nuclear magnetic resonance. The radio-frequency magnetic field created by the coil surrounding the sample and provided by the variable-frequency oscillator is perpendicular to the constant magnetic field created by the electromagnet. When the nuclei in the sample meet the resonance condition, the nuclei absorb energy from the radio-frequency field of the coil; this absorption changes the characteristics of the circuit in which the coil is included. Most modern NMR spectrometers use superconducting magnets at fixed field strengths and operate at frequencies of approximately 200 MHz.

Figure 44.22 is a color-enhanced MRI scan of a human brain, showing a tumor in white.
A nucleus is represented by the symbol $^{A}_{Z}X$, where $A$ is the mass number (the total number of nucleons) and $Z$ is the atomic number (the total number of protons). The total number of neutrons in a nucleus is the neutron number $N$, where $A = N + Z$. Nuclei having the same $Z$ value but different $A$ and $N$ values are isotopes of each other.

The magnetic moment of a nucleus is measured in terms of the nuclear magnetic moment $\mu_n$, where

$$\mu_n = \frac{e\hbar}{2m_p} = 5.05 \times 10^{-27} \text{ J/T} \quad (44.31)$$

The liquid-drop model of nuclear structure treats the nucleons as molecules in a drop of liquid. The four main contributions influencing binding energy are the volume effect, the surface effect, the Coulomb repulsion effect, and the symmetry effect. Summing such contributions results in the semiempirical binding-energy formula:

$$E_b = C_1A - C_2A^{2/3} - C_3\frac{Z(Z-1)}{A^{1/3}} - C_4\frac{(N-Z)^2}{A} \quad (44.3)$$

The shell model, or independent-particle model, assumes each nucleon exists in a shell and can only have discrete energy values. The stability of certain nuclei can be explained with this model.
A radioactive substance decays by **alpha decay, beta decay, or gamma decay**. An alpha particle is the \(^4\text{He}\) nucleus, a beta particle is either an electron \((e^-)\) or a positron \((e^+)\), and a gamma particle is a high-energy photon.

In alpha decay, a helium nucleus is ejected from the parent nucleus with a discrete set of kinetic energies. A nucleus undergoing beta decay emits either an electron \((e^-)\) and an antineutrino \((\bar{\nu})\) or a positron \((e^+)\) and a neutrino \((\nu)\). The electron or positron is ejected with a continuous range of energies. In **electron capture**, the nucleus of an atom absorbs one of its own electrons and emits a neutrino. In gamma decay, a nucleus in an excited state decays to its ground state and emits a gamma ray.

**Objective Questions**

1. In nuclear magnetic resonance, suppose we increase the value of the constant magnetic field. As a result, the frequency of the photons that are absorbed in a particular transition changes. How is the frequency of the photons absorbed related to the magnetic field? (a) The frequency is proportional to the square of the magnetic field. (b) The frequency is directly proportional to the magnetic field. (c) The frequency is inversely proportional to the magnetic field. (d) The frequency is proportional to the reciprocal of the square of the magnetic field.

2. When the \(^{86}\text{Kr}\) nucleus undergoes beta decay by emitting an electron and an antineutrino, does the daughter nucleus (Rb) contain (a) 58 neutrons and 37 protons, (b) 58 protons and 37 neutrons, (c) 54 neutrons and 41 protons, or (d) 55 neutrons and 40 protons?

3. When \(^{31}\text{P}\) decays to \(^{31}\text{S}\), which of the following particles is emitted? (a) a proton (b) an alpha particle (c) an electron (d) a gamma ray (e) an antineutrino

4. The half-life of radium-224 is about 3.6 days. What approximate fraction of a sample remains undecayed after two weeks? (a) \(\frac{1}{2}\) (b) \(\frac{1}{4}\) (c) \(\frac{1}{8}\) (d) \(\frac{1}{16}\) (e) \(\frac{1}{32}\)

5. Two samples of the same radioactive nuclide are prepared. Sample G has twice the initial activity of sample H. (i) How does the half-life of G compare with the half-life of H? (a) It is two times larger. (b) It is the same. (c) It is half as large. (ii) After each has passed through five half-lives, how do their activities compare? (a) G has more than twice the activity of H. (b) G has twice the activity of H. (c) G and H have the same activity. (d) G has lower activity than H.

6. If a radioactive nuclide \(^{A}\text{X}\) decays by emitting a gamma ray, what happens? (a) The resulting nuclide has a different Z value. (b) The resulting nuclide has the same A and Z values. (c) The resulting nuclide has a different A value. (d) Both A and Z decrease by one. (e) None of those statements is correct.

7. Does a nucleus designated as \(^{A}\text{X}\) contain (a) 20 neutrons and 20 protons, (b) 22 protons and 18 neutrons, (c) 18 protons and 22 neutrons, (d) 18 protons and 40 neutrons, or (e) 40 protons and 18 neutrons?

8. When \(^{144}\text{Nd}\) decays to \(^{140}\text{Ce}\), identify the particle that is released. (a) a proton (b) an alpha particle (c) an electron (d) a neutrino (e) a neutron

9. What is the \(Q\) value for the reaction \(^9\text{Be} + \alpha \rightarrow ^{12}\text{C} + n\)? (a) 8.4 MeV (b) 7.3 MeV (c) 6.2 MeV (d) 5.7 MeV (e) 4.2 MeV

10. (i) To predict the behavior of a nucleus in a fission reaction, which model would be more appropriate,
(a) the liquid-drop model or (b) the shell model?
(ii) Which model would be more successful in predicting the magnetic moment of a given nucleus? Choose from the same answers as in part (i).
(iii) Which could better explain the gamma-ray spectrum of an excited nucleus? Choose from the same answers as in part (i).

11. A free neutron has a half-life of 614 s. It undergoes beta decay by emitting an electron. Can a free proton undergo a similar decay? (a) yes, the same decay (b) yes, but by emitting a positron (c) yes, but with a very different half-life (d) no

12. Which of the following quantities represents the reaction energy of a nuclear reaction? (a) \((\text{final mass} - \text{initial mass})/c^2\) (b) \((\text{initial mass} - \text{final mass})/c^2\) (c) \((\text{final mass} - \text{initial mass})c^2\) (d) \((\text{initial mass} - \text{final mass})c^2\) (e) none of those quantities

13. In the decay \(^{234}\text{Th} \rightarrow ^{230}\text{Ra} + ^{4}\text{He}\), identify the mass number and the atomic number of the Ra nucleus: (a) \(A = 230, Z = 92\) (b) \(A = 238, Z = 88\) (c) \(A = 230, Z = 88\) (d) \(A = 234, Z = 88\) (e) \(A = 238, Z = 86\)

14. If a nucleus such as \(^{226}\text{Ra}\) initially at rest undergoes alpha decay, which has more kinetic energy after the decay, the alpha particle or the daughter nucleus? Explain your answer.

15. “If no more people were to be born, the law of population growth would strongly resemble the radioactive decay law.” Discuss this statement.

16. A student claims that a heavy form of hydrogen decays by alpha emission. How do you respond?

17. In beta decay, the energy of the electron or positron emitted from the nucleus lies somewhere in a relatively large range of possibilities. In alpha decay, however, the alpha-particle energy can only have discrete values. Explain this difference.

18. Can carbon-14 dating be used to measure the age of a rock? Explain.

19. In positron decay, a proton in the nucleus becomes a neutron and its positive charge is carried away by the positron. A neutron, though, has a larger rest energy than a proton. How is that possible?

20. (a) How many values of \(I_z\) are possible for \(I = \frac{5}{2}\)? (b) For \(I = \frac{3}{2}\)?

21. Why do nearly all the naturally occurring isotopes lie above the \(N = Z\) line in Figure 44.4?

22. Why are very heavy nuclei unstable?

23. Explain why nuclei that are well off the line of stability in Figure 44.4 tend to be unstable.

24. Consider two heavy nuclei X and Y having similar mass numbers. If X has the higher binding energy, which nucleus tends to be more unstable? Explain your answer.

25. What fraction of a radioactive sample has decayed after two half-lives have elapsed?

13. Figure CQ44.13 shows a watch from the early 20th century. The numbers and the hands of the watch are painted with a paint that contains a small amount of natural radium \(^{226}\text{Ra}\) mixed with a phosphorescent material. The decay of the radium causes the phosphorescent material to glow continuously. The radioactive nuclide \(^{226}\text{Ra}\) has a half-life of approximately \(1.60 \times 10^3\) years. Being that the solar system is approximately 5 billion years old, why was this isotope still available in the 20th century for use on this watch?

14. Can a nucleus emit alpha particles that have different energies? Explain.

15. In Rutherford’s experiment, assume an alpha particle is headed directly toward the nucleus of an atom. Why doesn’t the alpha particle make physical contact with the nucleus?

16. Suppose it could be shown that the cosmic-ray intensity at the Earth’s surface was much greater 10 000 years ago. How would this difference affect what we accept as valid carbon-dated values of the age of ancient samples of once-living matter? Explain your answer.

17. Compare and contrast the properties of a photon and a neutrino.
Section 44.1 Some Properties of Nuclei

1. Find the nuclear radii of (a) $^1_1$H, (b) $^{60}_{25}$Co, (c) $^{197}_{79}$Au, and (d) $^{239}_{94}$Pu.

2. (a) Determine the mass number of a nucleus whose radius is approximately equal to two-thirds the radius of $^{226}_{88}$Ra. (b) Identify the element. (c) Are any other answers possible? Explain.

3. (a) Use energy methods to calculate the distance of closest approach for a head-on collision between an alpha particle having an initial energy of 0.500 MeV and a gold nucleus ($^{197}_{79}$Au) at rest. Assume the gold nucleus remains at rest during the collision. (b) What minimum initial speed must the alpha particle have to approach as close as 300 fm to the gold nucleus?

4. (a) What is the order of magnitude of the number of protons in your body? (b) Of the number of neutrons? (c) Of the number of electrons?

5. Consider the $^{65}_{29}$Cu nucleus. Find approximate values for its (a) radius, (b) volume, and (c) density.

6. Using $2.30 \times 10^7$ kg/m$^3$ as the density of nuclear matter, find the radius of a sphere of such matter that would have a mass equal to that of a baseball, 0.145 kg.

7. A star ending its life with a mass of four to eight times the Sun’s mass is expected to collapse and then undergo a supernova event. In the remnant that is not carried away by the supernova explosion, protons and electrons combine to form a neutron star with approximately twice the mass of the Sun. Such a star can be thought of as a gigantic atomic nucleus. Assume $r = aA^{1/3}$ (Eq. 44.1). If a star of mass $3.98 \times 10^{30}$ kg is composed entirely of neutrons ($m_n = 1.67 \times 10^{-27}$ kg), what would its radius be?

8. Figure P44.8 shows the potential energy for two protons as a function of separation distance. In the text, it was claimed that, to be visible on such a graph, the peak in the curve is exaggerated by a factor of ten. (a) Find the electric potential energy of a pair of protons separated by 4.00 fm. (b) Verify that the peak in Figure P44.8 is exaggerated by a factor of ten.

9. Review. Singly ionized carbon is accelerated through 1 000 V and passed into a mass spectrometer to determine the isotopes present (see Chapter 29). The magnitude of the magnetic field in the spectrometer is 0.200 T. The orbit radius for a $^{12}$C isotope as it passes through the field is $r = 7.89$ cm. Find the radius of the orbit of a $^{13}$C isotope.

10. Review. Singly ionized carbon is accelerated through a potential difference $D$ and passed into a mass spectrometer to determine the isotopes present (see Chapter 29). The magnitude of the magnetic field in the spectrometer is $B$. The orbit radius for an isotope of mass $m_1$ as it passes through the field is $r$. Find the radius of the orbit of an isotope of mass $m_2$.

11. An alpha particle ($Z = 2$, mass = $6.64 \times 10^{-27}$ kg) approaches to within $1.00 \times 10^{-14}$ m of a carbon nucleus ($Z = 6$). What are (a) the magnitude of the maximum Coulomb force on the alpha particle, (b) the magnitude of the acceleration of the alpha particle at the time of the maximum force, and (c) the potential energy of the system of the alpha particle and the carbon nucleus at this time?

12. In a Rutherford scattering experiment, alpha particles having kinetic energy of 7.70 MeV are fired toward a gold nucleus that remains at rest during the collision. The alpha particles come as close as 29.5 fm to the gold nucleus before turning around. (a) Calculate the de Broglie wavelength for the 7.70-MeV alpha particle and compare it with the distance of closest approach,
13. Review. Two golf balls each have a 4.30-cm diameter and are 1.00 m apart. What would be the gravitational force exerted by each ball on the other if the balls were made of nuclear matter?

14. Assume a hydrogen atom is a sphere with diameter 0.100 nm and a hydrogen molecule consists of two such spheres in contact. (a) What fraction of the space in a tank of hydrogen gas at 0°C and 1.00 atm is occupied by the hydrogen molecules themselves? (b) What fraction of the space within one hydrogen atom is occupied by its nucleus, of radius 1.20 fm?

Section 44.2 Nuclear Binding Energy

15. Calculate the binding energy per nucleon for (a) \(^{2}\text{H}\), (b) \(^{4}\text{He}\), (c) \(^{56}\text{Fe}\), and (d) \(^{238}\text{U}\).

16. (a) Calculate the difference in binding energy per nucleon for the nuclei \(^{23}\text{Na}\) and \(^{25}\text{Mg}\). (b) How do you account for the difference?

17. A pair of nuclei for which \(Z_1 = N_2\) and \(Z_2 = N_1\) are called mirror isobars (the atomic and neutron numbers are interchanged). Binding-energy measurements on these nuclei can be used to obtain evidence of the charge independence of nuclear forces (that is, proton–proton, proton–neutron, and neutron–neutron nuclear forces are equal). Calculate the difference in binding energy for the two mirror isobars \(^{15}\text{O}\) and \(^{15}\text{N}\). The electric repulsion among eight protons rather than seven accounts for the difference.

18. The peak of the graph of nuclear binding energy per nucleon occurs near \(^{56}\text{Fe}\), which is why iron is prominent in the spectrum of the Sun and stars. Show that \(^{56}\text{Fe}\) has a higher binding energy per nucleon than its neighbors \(^{50}\text{Mn}\) and \(^{50}\text{Co}\).

19. Nuclei having the same mass numbers are called isobars. The isotope \(^{139}\text{La}\) is stable. A radioactive isobar, \(^{139}\text{Pr}\), is located below the line of stable nuclei as shown in Figure P44.19 and decays by e\(^-\) emission. Another radioactive isobar of \(^{139}\text{La}\), \(^{139}\text{Cs}\), decays by e\(^-\) emission and is located above the line of stable nuclei in Figure P44.19. (a) Which of these three isobars has the highest neutron-to-proton ratio? (b) Which has the greatest binding energy per nucleon? (c) Which do you expect to be heavier, \(^{139}\text{Pr}\) or \(^{139}\text{Cs}\)?

20. The energy required to construct a uniformly charged sphere of total charge \(Q\) and radius \(R\) is \(U = \frac{1}{2}kQ^2/R\), where \(k\) is the Coulomb constant (see Problem 77). Assume a \(^{40}\text{Ca}\) nucleus contains 20 protons uniformly distributed in a spherical volume. (a) How much energy is required to counter their electrical repulsion according to the above equation? (b) Calculate the binding energy of \(^{40}\text{Ca}\). (c) Explain what you can conclude from comparing the result of part (b) with that of part (a).

21. Calculate the minimum energy required to remove a neutron from the \(^{53}\text{Ca}\) nucleus.

Section 44.3 Nuclear Models

22. Using the graph in Figure 44.5, estimate how much energy is released when a nucleus of mass number 200 fissions into two nuclei each of mass number 100.

23. (a) Use the semiempirical binding-energy formula (Eq. 44.3) to compute the binding energy for \(^{56}\text{Fe}\). (b) What percentage is contributed to the binding energy by each of the four terms?

24. (a) In the liquid-drop model of nuclear structure, why does the surface-effect term \(-C_2A^{2/3}\) have a negative sign? (b) What If? The binding energy of the nucleus increases as the volume-to-surface area ratio increases. Calculate this ratio for both spherical and cubical shapes and explain which is more plausible for nuclei.

Section 44.4 Radioactivity

25. What time interval is required for the activity of a sample of the radioactive isotope \(^{73}\text{As}\) to decrease by 90.0% from its original value? The half-life of \(^{73}\text{As}\) is 26 h.

26. A freshly prepared sample of a certain radioactive isotope has an activity of 10.0 mCi. After 4.00 h, its activity is 8.00 mCi. Find (a) the decay constant and (b) the half-life. (c) How many atoms of the isotope were contained in the freshly prepared sample? (d) What is the sample’s activity 30.0 h after it is prepared?

27. A sample of radioactive material contains \(1.00 \times 10^{15}\) atoms and has an activity of \(6.00 \times 10^{01}\) Bq. What is its half-life?

28. From the equation expressing the law of radioactive decay, derive the following useful expressions for the decay constant and the half-life, in terms of the time interval \(\Delta t\) during which the decay rate decreases from \(R_0\) to \(R\):

\[
\lambda = \frac{1}{\Delta t} \ln \left( \frac{R_0}{R} \right) \quad T_{1/2} = \frac{(\ln 2) \Delta t}{\ln \left( R_0/R \right)}
\]
29. The radioactive isotope $^{198}$Au has a half-life of 64.8 h. A sample containing this isotope has an initial activity ($t = 0$) of 40.0 mCi. Calculate the number of nuclei that decay in the time interval between $t_1 = 10.0$ h and $t_2 = 12.0$ h.

30. A radioactive nucleus has half-life $T_{1/2}$. A sample containing these nuclei has initial activity $R_0$ at $t = 0$. Calculate the number of nuclei that decay during the interval between the later times $t_1$ and $t_2$.

31. The half-life of $^{131}$I is 8.04 days. (a) Calculate the decay constant for this nuclide. (b) Find the number of $^{131}$I nuclei necessary to produce a sample with an activity of 6.40 mCi. (c) A sample of $^{131}$I with this initial activity decays for 40.2 d. What is the activity at the end of that period?

32. Tritium has a half-life of 12.33 years. What fraction of the nuclei in a tritium sample will remain (a) after 5.00 yr? (b) After 10.0 yr? (c) After 123.3 yr? (d) According to Equation 44.46, an infinite amount of time is required for the entire sample to decay. Discuss whether that is realistic.

33. Consider a radioactive sample. Determine the ratio of the number of nuclei decaying during the first half of its half-life to the number of nuclei decaying during the second half of its half-life.

34. (a) The daughter nucleus formed in radioactive decay is often radioactive. Let $N_p$ represent the number of parent nuclei at time $t = 0$, $N_i$ the number of parent nuclei at time $t$, and $N_1$ the decay constant of the parent. Suppose the number of daughter nuclei at time $t = 0$ is zero. Let $N_d(t)$ be the number of daughter nuclei at time $t$ and let $N_d$ be the decay constant of the daughter. Show that $N_d(t)$ satisfies the differential equation

$$\frac{dN_d}{dt} = N_p N_1 - N_2 N_2$$

(b) Verify by substitution that this differential equation has the solution

$$N_d(t) = N_p \frac{N_1}{N_2} \left( e^{-N_1 t} - e^{-N_2 t} \right)$$

This equation is the law of successive radioactive decays. (c) $^{210}$Po decays into $^{210}$Pb with a half-life of 3.0 min, and $^{210}$Pb decays into $^{210}$Bi with a half-life of 26.8 min. On the same axes, plot graphs of $N_1$ for $^{210}$Po and $N_d$ for $^{210}$Pb. Let $N_p = 1 \times 10^3$ nuclei and choose values of $t$ from 0 to 36 min in 2-min intervals. (d) The curve for $^{210}$Pb obtained in part (c) at first rises to a maximum and then starts to decay. At what instant $t_0$ is the number of $^{210}$Pb nuclei a maximum? (e) By applying the condition for a maximum $\frac{dN_d}{dt} = 0$, derive a symbolic equation for $t_0$ in terms of $N_1$ and $N_2$. (f) Explain whether the value obtained in part (c) agrees with this equation.

### Section 44.5 The Decay Processes

35. Determine which decays can occur spontaneously.

(a) $^{38}$Ca $\rightarrow$ $^{40}$K + $^{16}$O

(b) $^{40}$Ar $\rightarrow$ $^{40}$K + $^{16}$O

(c) $^{108}$Mo $\rightarrow$ $^{104}$Ge + $^{12}$He

36. A $^3$H nucleus beta decays into $^3$He by creating an electron and an antineutrino according to the reaction

$$^3H \rightarrow \ ^3He + e^- + \bar{\nu}$$

Determine the total energy released in this decay.

37. The $^{14}$C isotope undergoes beta decay according to the process given by Equation 44.21. Find the $Q$ value for this process.

38. Identify the unknown nuclide or particle (X).

(a) $X \rightarrow 67^{54}$Ni + $\gamma$

(b) $^{215}$Po $\rightarrow$ X + $\alpha$

(c) $X \rightarrow 56^{54}$Fe + $e^+ + \nu$

39. Find the energy released in the alpha decay

$$^{238}_{92}$U $\rightarrow$ $^{234}_{90}$Th + $^4$He

40. A sample consists of $1.00 \times 10^6$ radioactive nuclei with a half-life of 10.0 h. No other nuclei are present at time $t = 0$. The stable daughter nuclei accumulate in the sample as time goes on. (a) Derive an equation giving the number of daughter nuclei $N_d$ as a function of time. (b) Sketch or describe a graph of the number of daughter nuclei as a function of time. (c) What are the maximum and minimum numbers of daughter nuclei, and when do they occur? (d) What are the maximum and minimum rates of change in the number of daughter nuclei, and when do they occur?

41. The nucleus $^{15}$O decays by electron capture. The nuclear reaction is written

$$^{15}$O + $e^-$ $\rightarrow$ $^{15}$N + $\nu$

(a) Write the process going on for a single particle within the nucleus. (b) Disregarding the daughter’s recoil, determine the energy of the neutrino.

42. A living specimen in equilibrium with the atmosphere contains one atom of $^{14}$C (half-life = 5730 yr) for every 7.70 x $10^{11}$ stable carbon atoms. An archeological sample of wood (cellulose, $\text{C}_6\text{H}_{10}\text{O}_5$) contains 21.0 mg of carbon. When the sample is placed inside a shielded beta counter with 88.0% counting efficiency, 837 counts are accumulated in one week. We wish to find the age of the sample. (a) Find the number of carbon atoms in the sample. (b) Find the number of carbon-14 atoms in the sample. (c) Find the decay constant for carbon-14 in inverse seconds. (d) Find the initial number of decays per week just after the specimen died. (e) Find the corrected number of decays per week from the current sample. (f) From the answers to parts (d) and (e), find the time interval in years since the specimen died.

### Section 44.6 Natural Radioactivity

43. Uranium is naturally present in rock and soil. At one step in its series of radioactive decays, $^{238}$U produces the chemically inert gas radon-222, with a half-life of 3.82 days. The radon seeps out of the ground to mix into the atmosphere, typically making open air radioactive with activity 0.3 pCi/L. In homes, $^{222}$Rn can be a serious pollutant, accumulating to reach much higher
activities in enclosed spaces, sometimes reaching 4.00 pCi/L. If the radon radioactivity exceeds 4.00 pCi/L, the U.S. Environmental Protection Agency suggests taking action to reduce it such as by reducing infiltration of air from the ground. (a) Convert the activity 4.00 pCi/L to units of becquerels per cubic meter. (b) How many \(^{222}\text{Rn}\) atoms are in 1 m\(^3\) of air displaying this activity? (c) What fraction of the mass of the air does the radon constitute?  

44. The most common isotope of radon is \(^{222}\text{Rn}\), which has half-life 3.82 days. (a) What fraction of the nuclei that were on the Earth one week ago are now undecayed? (b) Of those that existed one year ago? (c) In view of these results, explain why radon remains a problem, contributing significantly to our background radiation exposure.  

45. Enter the correct nuclide symbol in each open tan rectangle in Figure P44.45, which shows the sequences of decays in the natural radioactive series starting with the long-lived isotope uranium-235 and ending with the stable nucleus lead-207.

![Figure P44.45](image_url)

46. A rock sample contains traces of \(^{238}\text{U}\), \(^{235}\text{U}\), \(^{232}\text{Th}\), \(^{208}\text{Pb}\), \(^{207}\text{Pb}\), and \(^{206}\text{Pb}\). Analysis shows that the ratio of the amount of \(^{238}\text{U}\) to \(^{208}\text{Pb}\) is 1.164. (a) Assuming the rock originally contained no lead, determine the age of the rock. (b) What should be the ratios of \(^{235}\text{U}\) to \(^{207}\text{Pb}\) and of \(^{232}\text{Th}\) to \(^{206}\text{Pb}\) so that they would yield the same age for the rock? Ignore the minute amounts of the intermediate decay products in the decay chains. Note: This form of multiple dating gives reliable geological dates.  

47. A beam of 6.61-MeV protons is incident on a target of \(^{27}\text{Al}\). Those that collide produce the reaction \[ \text{p} + \frac{27}{13}\text{Al} \rightarrow \frac{27}{14}\text{Si} + n \]  

Ignoring any recoil of the product nucleus, determine the kinetic energy of the emerging neutrons.  

48. (a) One method of producing neutrons for experimental use is bombardment of light nuclei with alpha particles. In the method used by James Chadwick in 1932, alpha particles emitted by polonium are incident on beryllium nuclei:

\[ \frac{3}{2}\text{He} + \frac{7}{4}\text{Be} \rightarrow \frac{13}{2}\text{C} + \frac{1}{0}\text{n} \]

What is the \(Q\) value of this reaction? (b) Neutrons are also often produced by small-particle accelerators. In one design, deuterons accelerated in a Van de Graaff generator bombard other deuterium nuclei and cause the reaction

\[ \frac{2}{1}\text{H} + \frac{2}{1}\text{H} \rightarrow \frac{3}{2}\text{He} + \frac{1}{0}\text{n} \]

Calculate the \(Q\) value of the reaction. (c) Is the reaction in part (b) exothermic or endothermic?  

49. Identify the unknown nuclides and particles X and \(X’\) in the nuclear reactions (a) \(X + \frac{3}{2}\text{He} \rightarrow \frac{4}{2}\text{Mg} + \frac{1}{0}\text{n}\), (b) \(\frac{235}{92}\text{U} + \frac{1}{0}\text{n} \rightarrow \frac{90}{36}\text{Sr} + X + 2(\frac{1}{0}\text{n})\), and (c) \(2(\frac{1}{1}\text{H}) \rightarrow \frac{3}{2}\text{H} + X + X’\).  

50. Natural gold has only one isotope, \(^{197}\text{Au}\). If natural gold is irradiated by a flux of slow neutrons, electrons are emitted. (a) Write the reaction equation. (b) Calculate the maximum energy of the emitted electrons.  

51. The following reactions are observed:

\[ \frac{8}{10}\text{Be} + \text{n} \rightarrow \frac{9}{10}\text{Be} + \gamma \quad Q = 6.812 \text{ MeV} \]
\[ \frac{9}{10}\text{Be} + \gamma \rightarrow \frac{8}{10}\text{Be} + \text{n} \quad Q = -1.665 \text{ MeV} \]

Calculate the masses of \(^8\text{Be}\) and \(^9\text{Be}\) in unified mass units to four decimal places from these data.  

### Section 44.8 Nuclear Magnetic Resonance and Magnetic Resonance Imaging  

52. Construct a diagram like that of Figure 44.19 for the cases when \(I\) equals (a) \(\frac{1}{2}\) and (b) 4.  

53. The radio frequency at which a nucleus having a magnetic moment of magnitude \(\mu\) displays resonance absorption between spin states is called the Larmor frequency and is given by

\[ f = \frac{\Delta E}{h} = \frac{2\mu B}{h} \]

Calculate the Larmor frequency for (a) free neutrons in a magnetic field of 1.00 T, (b) free protons in a magnetic field of 1.00 T, and (c) free protons in the Earth’s magnetic field at a location where the magnitude of the field is 50.0 \(\mu\)T.  

### Additional Problems  

54. A wooden artifact is found in an ancient tomb. Its carbon-14 \(^{14}\text{C}\) activity is measured to be 60.0% of that in a fresh sample of wood from the same region.
Assuming the same amount of $^{14}$C was initially present in the artifact as is now contained in the fresh sample, determine the age of the artifact.

55. A 200.0-mCi sample of a radioactive isotope is purchased by a medical supply house. If the sample has a half-life of 14.0 days, how long will it be before its activity is reduced to 20.0 mCi?

56. Why is the following situation impossible? A $^{19}$B nucleus is struck by an incoming alpha particle. As a result, a proton and a $^{12}$C nucleus leave the site after the reaction.

57. (a) Find the radius of the $^{12}$C nucleus. (b) Find the force of repulsion between a proton at the surface of a $^{12}$C nucleus and the remaining five protons. (c) How much work (in MeV) has to be done to overcome this electric repulsion in transporting the last proton from a large distance up to the surface of the nucleus? (d) Repeat parts (a), (b), and (c) for $^{6}$Li.

58. (a) Why is the beta decay $p \rightarrow n + e^+ + \nu$ forbidden for a free proton? (b) What if? Why is the same reaction possible if the proton is bound in a nucleus? For example, the following reaction occurs:

$$^{12}\text{N} \rightarrow ^{12}\text{C} + e^+ + \nu$$

(c) How much energy is released in the reaction given in part (b)?

59. Review. Consider the Bohr model of the hydrogen atom, with the electron in the ground state. The magnetic field at the nucleus produced by the orbiting electron has a value of 12.5 T. (See Problem 6 in Chapter 30.) The proton can have its magnetic moment aligned in either of two directions perpendicular to the plane of the electron’s orbit. The interaction of the proton’s magnetic moment with the electron’s magnetic field causes a difference in energy between the states with the two different orientations of the proton’s magnetic moment. Find that energy difference in electron volts.

60. Show that the $^{238}$U isotope cannot spontaneously emit a proton by analyzing the hypothetical process

$$^{238}\text{U} \rightarrow ^{237}\text{Pa} + ^1\text{H}$$

*Note:* The $^{237}$Pa isotope has a mass of 237.051 144 u.

61. Review. (a) Is the mass of a hydrogen atom in its ground state larger or smaller than the sum of the masses of a proton and an electron? (b) What is the mass difference? (c) How large is the difference as a percentage of the total mass? (d) Is it large enough to affect the value of the atomic mass listed to six decimal places in Table 44.2?

62. Why is the following situation impossible? In an effort to study positronium, a scientist places $^{57}$Co and $^{14}$C in proximity. The $^{57}$Co nuclei decay by $e^-$ emission, and the $^{14}$C nuclei decay by $e^-$ emission. Some of the positrons and electrons from these decays combine to form sufficient amounts of positronium for the scientist to gather data.

63. A by-product of some fission reactors is the isotope $^{239}$Pu, an alpha emitter having a half-life of 24 120 yr:

$$^{239}\text{Pu} \rightarrow ^{235}\text{U} + \alpha$$

Consider a sample of 1.00 kg of pure $^{239}$Pu at $t = 0$. Calculate (a) the number of $^{239}$Pu nuclei present at $t = 0$ and (b) the initial activity in the sample. (c) What if? For what time interval does the sample have to be stored if a “safe” activity level is 0.100 Bq?

64. After the sudden release of radioactivity from the Chernobyl nuclear reactor accident in 1986, the radioactivity of milk in Poland rose to 2 000 Bq/L due to iodine-131 present in the grass eaten by dairy cattle. Radioactive iodine, with half-life 8.04 days, is particularly hazardous because the thyroid gland concentrates iodine. The Chernobyl accident caused a measurable increase in thyroid cancers among children in Poland and many other Eastern European countries. (a) For comparison, find the activity of milk due to potassium. Assume 1.00 liter of milk contains 2.00 g of potassium, of which 0.011 7% is the isotope $^{40}$K with half-life $1.28 \times 10^5$ yr. (b) After what elapsed time would the activity due to iodine fall below that due to potassium?

65. A theory of nuclear astrophysics proposes that all the elements heavier than iron are formed in supernova explosions ending the lives of massive stars. Assume equal amounts of $^{235}$U and $^{238}$U were created at the time of the explosion and the present $^{235}$U/$^{238}$U ratio on the Earth is 0.007 25. The half-lives of $^{235}$U and $^{238}$U are $0.704 \times 10^9$ yr and $4.47 \times 10^9$ yr, respectively. How long ago did the star(s) explode that released the elements that formed the Earth?

66. The activity of a radioactive sample was measured over 12 h, with the net count rates shown in the accompanying table. (a) Plot the logarithm of the counting rate as a function of time. (b) Determine the decay constant and half-life of the radioactive nuclei in the sample. (c) What counting rate would you expect for the sample at $t = 0$? (d) Assuming the efficiency of the counting instrument is 10.0%, calculate the number of radioactive atoms in the sample at $t = 0$.

67. When, after a reaction or disturbance of any kind, a nucleus is left in an excited state, it can return to its normal (ground) state by emission of a gamma-ray photon (or several photons). This process is illustrated by Equation 44.25. The emitting nucleus must recoil to
conserve both energy and momentum. (a) Show that the recoil energy of the nucleus is

\[ E_r = \frac{(\Delta E)^2}{2Mc^2} \]

where \( \Delta E \) is the difference in energy between the excited and ground states of a nucleus of mass \( M \).
(b) Calculate the recoil energy of the \( ^{52}\text{Fe} \) nucleus when it decays by gamma emission from the 14.4-keV excited state. For this calculation, take the mass to be 57 u. Suggestion: Assume \( hf << Mc^2 \).

68. In a piece of rock from the Moon, the \( ^{87}\text{Rb} \) content is assayed to be \( 1.82 \times 10^{10} \) atoms per gram of material and the \( ^{87}\text{Sr} \) content is found to be \( 1.07 \times 10^6 \) atoms per gram. The relevant decay relating these nuclides is \( ^{87}\text{Rb} \rightarrow ^{87}\text{Sr} + e^- + \gamma \). The half-life of the decay is \( 4.75 \times 10^1 \) yr. (a) Calculate the age of the rock. (b) What If? Could the material in the rock actually be much older? What assumption is implicit in using the radioactive dating method?

69. Free neutrons have a characteristic half-life of 10.4 min. What fraction of a group of free neutrons with kinetic energy 0.0400 eV decays before traveling a distance of 10.0 km?

70. On July 4, 1054, a brilliant light appeared in the constellation Taurus the Bull. The supernova, which could be seen in daylight for some days, was recorded by Arab and Chinese astronomers. As it faded, it remained visible for years, dimming for a time with the 77.1-day half-life of the radioactive cobalt-56 that had been created in the explosion. (a) The remains of the star now form the Crab nebula (see the photograph opening Chapter 34). In it, the cobalt-56 has now decreased to what fraction of its original activity? (b) Suppose that an American, of the people called the Anasazi, made a charcoal drawing of the supernova. The carbon-14 in the charcoal has now decayed to what fraction of its original activity?

71. When a nucleus decays, it can leave the daughter nucleus in an excited state. The \( ^{43}\text{Tc} \) nucleus (molar mass 92.910 2 g/mol) in the ground state decays by electron capture and \( e^+ \) emission to energy levels of the daughter (molar mass 92.906 8 g/mol in the ground state) at 2.44 MeV, 2.03 MeV, 1.48 MeV, and 1.35 MeV. (a) Identify the daughter nuclide. (b) To which of the listed levels of the daughter are electron capture and \( e^+ \) decay of \( ^{43}\text{Tc} \) allowed?

72. The radioactive isotope \( ^{137}\text{Ba} \) has a relatively short half-life and can be easily extracted from a solution containing its parent \( ^{137}\text{Cs} \). This barium isotope is commonly used in an undergraduate laboratory exercise for demonstrating the radioactive decay law. Undergraduate students using modest experimental equipment took the data presented in Figure P44.72. Determine the half-life for the decay of \( ^{137}\text{Ba} \) using their data.

Figure P44.72

73. As part of his discovery of the neutron in 1932, James Chadwick determined the mass of the newly identified particle by firing a beam of fast neutrons, all having the same speed, at two different targets and measuring the maximum recoil speeds of the target nuclei. The maximum speeds arise when an elastic head-on collision occurs between a neutron and a stationary target nucleus. (a) Represent the masses and final speeds of the two target nuclei as \( m_1, v_1, m_2, \) and \( v_2 \) and assume Newtonian mechanics applies. Show that the neutron mass can be calculated from the equation

\[ m_n = \frac{m_1 v_1 - m_2 v_2}{v_2 - v_1} \]

(b) Chadwick directed a beam of neutrons (produced from a nuclear reaction) on paraffin, which contains hydrogen. The maximum speed of the protons ejected was found to be \( 3.30 \times 10^7 \) m/s. Because the velocity of the neutrons could not be determined directly, a second experiment was performed using neutrons from the same source and nitrogen nuclei as the target. The maximum recoil speed of the nitrogen nuclei was found to be \( 4.70 \times 10^7 \) m/s. The masses of a proton and a nitrogen nucleus were taken as 1.00 u and 14.0 u, respectively. What was Chadwick’s value for the neutron mass?

74. When the nuclear reaction represented by Equation 44.28 is endothermic, the reaction energy \( Q \) is negative. For the reaction to proceed, the incoming particle must have a minimum energy called the threshold energy, \( E_{th} \). Some fraction of the energy of the incident particle is transferred to the compound nucleus to conserve momentum. Therefore, \( E_{th} \) must be greater than \( Q \). (a) Show that

\[ E_{th} = -Q \left( 1 + \frac{M_a}{M_X} \right) \]
(b) Calculate the threshold energy of the incident alpha particle in the reaction
\[ ^4\text{He} + ^7\text{Li} \rightarrow ^{11}\text{O} + ^1\text{H} \]

75. In an experiment on the transport of nutrients in a plant’s root structure, two radioactive nuclides X and Y are used. Initially, 2.50 times more nuclei of type X are present than of type Y. At a time 3.00 d later, there are 4.20 times more nuclei of type X than of type Y. Isotope Y has a half-life of 1.60 d. What is the half-life of isotope X?

76. In an experiment on the transport of nutrients in a plant’s root structure, two radioactive nuclides X and Y are used. Initially, the ratio of the number of nuclei of type X present to that of type Y is \( r_1 \). After a time interval \( \Delta t \), the ratio of the number of nuclei of type X present to that of type Y is \( r_2 \). Isotope Y has a half-life of \( T_Y \). What is the half-life of isotope X?

**Challenge Problems**

77. **Review.** Consider a model of the nucleus in which the positive charge \( (Ze) \) is uniformly distributed throughout a sphere of radius \( R \). By integrating the energy density \( \frac{1}{2}\epsilon_0E^2 \) over all space, show that the electric potential energy may be written

\[ U = \frac{3Z^2e^4}{20\pi\epsilon_0R} = \frac{3ke^2}{5R} \]

Problem 72 in Chapter 25 derived the same result by a different method.

78. After determining that the Sun has existed for hundreds of millions of years, but before the discovery of nuclear physics, scientists could not explain why the Sun has continued to burn for such a long time interval. For example, if it were a coal fire, it would have burned up in about 3000 yr. Assume the Sun, whose mass is equal to \( 1.99 \times 10^{30} \) kg, originally consisted entirely of hydrogen and its total power output is \( 3.85 \times 10^{26} \) W. (a) Assuming the energy-generating mechanism of the Sun is the fusion of hydrogen into helium via the net reaction

\[ 4(\text{H}) + 2(e^-) \rightarrow ^4\text{He} + 2\nu + \gamma \]

calculate the energy (in joules) given off by this reaction. (b) Take the mass of one hydrogen atom to be equal to \( 1.67 \times 10^{-27} \) kg. Determine how many hydrogen atoms constitute the Sun. (c) If the total power output remains constant, after what time interval will all the hydrogen be converted into helium, making the Sun die? (d) How does your answer to part (c) compare with current estimates of the expected life of the Sun, which are 4 billion to 7 billion years?
In this chapter, we study two means for deriving energy from nuclear reactions: fission, in which a large nucleus splits into two smaller nuclei, and fusion, in which two small nuclei fuse to form a larger one. In both cases, the released energy can be used either constructively (as in electric power plants) or destructively (as in nuclear weapons). We also examine the ways in which radiation interacts with matter and discuss the structure of fission and fusion reactors. The chapter concludes with a discussion of some industrial and biological applications of radiation.

45.1 Interactions Involving Neutrons

Nuclear fission is the process that occurs in present-day nuclear reactors and ultimately results in energy supplied to a community by electrical transmission. Nuclear fusion is an area of active research, but it has not yet been commercially developed for the supply of energy. We will discuss fission first and then explore fusion in Section 45.4.

To understand nuclear fission and the physics of nuclear reactors, we must first understand how neutrons interact with nuclei. Because of their charge neutrality, neutrons are not subject to Coulomb forces and as a result do not interact electri-
cally with electrons or the nucleus. Therefore, neutrons can easily penetrate deep into an atom and collide with the nucleus.

A fast neutron (energy greater than approximately 1 MeV) traveling through matter undergoes many collisions with nuclei, giving up some of its kinetic energy in each collision. For fast neutrons in some materials, elastic collisions dominate. Materials for which that occurs are called moderators because they slow down (or moderate) the originally energetic neutrons very effectively. Moderator nuclei should be of low mass so that a large amount of kinetic energy is transferred to them when struck by neutrons. For this reason, materials that are abundant in hydrogen, such as paraffin and water, are good moderators for neutrons.

Eventually, most neutrons bombarding a moderator become thermal neutrons, which means they have given up so much of their energy that they are in thermal equilibrium with the moderator material. Their average kinetic energy at room temperature is, from Equation 21.19,

\[ K_{\text{avg}} = \frac{\frac{2}{3} k_B T}{2} = \frac{2}{3} (1.38 \times 10^{-23} \text{ J/K})(300 \text{ K}) = 6.21 \times 10^{-21} \text{ J} \approx 0.04 \text{ eV} \]

which corresponds to a neutron root-mean-square speed of approximately 2 800 m/s. Thermal neutrons have a distribution of speeds, just as the molecules in a container of gas do (see Chapter 21). High-energy neutrons, those with energy of several MeV, thermalize (that is, their average energy reaches \( K_{\text{avg}} \)) in less than 1 ms when they are incident on a moderator.

Once the neutrons have thermalized and the energy of a particular neutron is sufficiently low, there is a high probability the neutron will be captured by a nucleus, an event that is accompanied by the emission of a gamma ray. This neutron capture reaction can be written

\[ ^{1}_1n + ^{2}_1X \rightarrow ^{A+1}_2X^* \rightarrow ^{A+1}_2X + \gamma \] \hspace{1cm} (45.1)

Once the neutron is captured, the nucleus \( ^{A+1}_2X^* \) is in an excited state for a very short time before it undergoes gamma decay. The product nucleus \( ^{A+1}_2X \) is usually radioactive and decays by beta emission.

The neutron-capture rate for neutrons passing through any sample depends on the type of atoms in the sample and on the energy of the incident neutrons. The interaction of neutrons with matter increases with decreasing neutron energy because a slow neutron spends a larger time interval in the vicinity of target nuclei.

\section*{45.2 Nuclear Fission}

As mentioned in Section 44.2, nuclear fission occurs when a heavy nucleus, such as \(^{235}\text{U}\), splits into two smaller nuclei. Fission is initiated when a heavy nucleus captures a thermal neutron as described by the first step in Equation 45.1. The absorption of the neutron creates a nucleus that is unstable and can change to a lower-energy configuration by splitting into two smaller nuclei. In such a reaction, the combined mass of the daughter nuclei is less than the mass of the parent nucleus, and the difference in mass is called the mass defect. Multiplying the mass defect by \( c^2 \) gives the numerical value of the released energy. This energy is in the form of kinetic energy associated with the motion of the neutrons and the daughter nuclei after the fission event. Energy is released because the binding energy per nucleon of the daughter nuclei is approximately 1 MeV greater than that of the parent nucleus (see Fig. 44.5).

Nuclear fission was first observed in 1938 by Otto Hahn (1879–1968) and Fritz Strassmann (1902–1980) following some basic studies by Fermi. After bombarding uranium with neutrons, Hahn and Strassmann discovered among the reaction products two medium-mass elements, barium and lanthanum. Shortly thereafter, Lise Meitner (1878–1968) and her nephew Otto Frisch (1904–1979) explained what had happened. After absorbing a neutron, the uranium nucleus had split into two

\section*{Pitfall Prevention 45.1}

\textbf{Binding Energy Reminder} Remember from Chapter 44 that binding energy is the absolute value of the system energy and is related to the system mass. Therefore, when considering Figure 44.5, imagine flipping it upside down for a graph representing system mass. In a fission reaction, the system mass decreases. This decrease in mass appears in the system as kinetic energy of the fission products.
nearly equal fragments plus several neutrons. Such an occurrence was of considerable interest to physicists attempting to understand the nucleus, but it was to have even more far-reaching consequences. Measurements showed that approximately 200 MeV of energy was released in each fission event, and this fact was to affect the course of history in World War II.

The fission of $^{235}$U by thermal neutrons can be represented by the reaction

$$^{1}_{0}n + ^{235}_{92}U \rightarrow ^{236}_{92}U^* \rightarrow X + Y + \text{neutrons} \quad (45.2)$$

where $^{236}_{92}U^*$ is an intermediate excited state that lasts for approximately $10^{-12}$ s before splitting into medium-mass nuclei $X$ and $Y$, which are called fission fragments. In any fission reaction, there are many combinations of $X$ and $Y$ that satisfy the requirements of conservation of energy and charge. In the case of uranium, for example, approximately 90 daughter nuclei can be formed.

Fission also results in the production of several neutrons, typically two or three. On average, approximately 2.5 neutrons are released per event. A typical fission reaction for uranium is

$$^{1}_{0}n + ^{235}_{92}U \rightarrow ^{141}_{56}Ba + ^{92}_{56}Kr + 3(^{1}_{0}n) \quad (45.3)$$

Figure 45.1 shows a pictorial representation of the fission event in Equation 45.3.

Figure 45.2 is a graph of the distribution of fission products versus mass number $A$. The most probable products have mass numbers $A \approx 95$ and $A \approx 140$. Suppose these products are $^{95}_{39}Y$ (with 56 neutrons) and $^{140}_{53}I$ (with 87 neutrons). If these nuclei are located on the graph of Figure 44.4, it is seen that both are well above the line of stability. Because these fragments are very unstable owing to their unusually high number of neutrons, they almost instantaneously release two or three neutrons.

Let’s estimate the disintegration energy $Q$ released in a typical fission process. From Figure 44.5, we see that the binding energy per nucleon is approximately 7.2 MeV for heavy nuclei ($A < 240$) and approximately 8.2 MeV for nuclei of intermediate mass. The amount of energy released is $8.2 \text{ MeV} - 7.2 \text{ MeV} = 1 \text{ MeV}$ per nucleon. Because there are a total of 235 nucleons in $^{235}_{92}U$, the energy released per fission event is approximately 235 MeV, a large amount of energy relative to the amount released in chemical processes. For example, the energy released in the combustion of one molecule of octane used in gasoline engines is about one-millionth of the energy released in a single fission event!

Quick Quiz 45.1 When a nucleus undergoes fission, the two daughter nuclei are generally radioactive. By which process are they most likely to decay? (a) alpha decay (b) beta decay ($e^{-}$) (c) beta decay ($e^{+}$)

Quick Quiz 45.2 Which of the following are possible fission reactions?

(a) $^{1}_{0}n + ^{235}_{92}U \rightarrow ^{140}_{54}Xe + ^{94}_{56}Sr + 2(^{1}_{0}n)$

(b) $^{1}_{0}n + ^{235}_{92}U \rightarrow ^{132}_{55}Sn + ^{101}_{42}Mo + 3(^{1}_{0}n)$

(c) $^{1}_{0}n + ^{239}_{94}Pu \rightarrow ^{157}_{53}I + ^{97}_{41}Nb + 3(^{1}_{0}n)$

Example 45.1 The Energy Released in the Fission of $^{235}$U

Calculate the energy released when 1.00 kg of $^{235}$U fissions, taking the disintegration energy per event to be $Q = 208 \text{ MeV}$.

Solution

Conceptualize Imagine a nucleus of $^{235}$U absorbing a neutron and then splitting into two smaller nuclei and several neutrons as in Figure 45.1.
In Section 45.2, we learned that when $^{235}\text{U}$ fissions, one incoming neutron results in an average of 2.5 neutrons emitted per event. These neutrons can trigger other nuclei to fission. Because more neutrons are produced by the event than are absorbed, there is the possibility of an ever-building chain reaction (Fig. 45.3).

**Categorize** The problem statement tells us to categorize this example as one involving an energy analysis of nuclear fission.

**Analyze** Because $A = 235$ for uranium, one mole of this isotope has a mass of $M = 235$ g.

Find the number of nuclei in our sample in terms of the number of moles $n$ and Avogadro's number, and then in terms of the sample mass $m$ and the molar mass $M$ of $^{235}\text{U}$:

$$N = nN_A = \frac{m}{M}N_A$$

Find the total energy released when all nuclei undergo fission:

$$E = NQ = \frac{m}{M}N_AQ = \frac{1.00 \times 10^3}{235 \text{ g/mol}}(6.02 \times 10^{23} \text{ mol}^{-1})(208 \text{ MeV})$$

$$= 5.33 \times 10^{26} \text{ MeV}$$

**Finalize** Convert this energy to kWh:

$$E = (5.33 \times 10^{26} \text{ MeV})\left(\frac{1.60 \times 10^{-13} \text{ J}}{1 \text{ MeV}}\right)\left(\frac{1 \text{ kWh}}{\frac{1 \text{ MeV}}{3.60 \times 10^6 \text{ J}}}\right) = 2.37 \times 10^7 \text{ kWh}$$

which, if released slowly, is enough energy to keep a 100-W lightbulb operating for 30 000 years! If the available fission energy in 1 kg of $^{235}\text{U}$ were suddenly released, it would be equivalent to detonating about 20 000 tons of TNT.

**45.3 Nuclear Reactors**

In Section 45.2, we learned that when $^{235}\text{U}$ fissions, one incoming neutron results in an average of 2.5 neutrons emitted per event. These neutrons can trigger other nuclei to fission. Because more neutrons are produced by the event than are absorbed, there is the possibility of an ever-building chain reaction (Fig. 45.3). Experience shows that if the chain reaction is not controlled (that is, if it does not
proceed slowly, it can result in a violent explosion, with the sudden release of an enormous amount of energy. When the reaction is controlled, however, the energy released can be put to constructive use. In the United States, for example, nearly 20% of the electricity generated each year comes from nuclear power plants, and nuclear power is used extensively in many other countries, including France, Russia, and India.

A nuclear reactor is a system designed to maintain what is called a self-sustained chain reaction. This important process was first achieved in 1942 by Enrico Fermi and his team at the University of Chicago, using naturally occurring uranium as the fuel. In the first nuclear reactor (Fig. 45.4), Fermi placed bricks of graphite (carbon) between the fuel elements. Carbon nuclei are about 12 times more massive than neutrons, but after several collisions with carbon nuclei, a neutron is slowed sufficiently to increase its likelihood of fission with 235U. In this design, carbon is the moderator; most modern reactors use water as the moderator.

Most reactors in operation today also use uranium as fuel. Naturally occurring uranium contains only 0.7% of the 235U isotope, however, with the remaining 99.3% being 238U. This fact is important to the operation of a reactor because 238U almost never fissions. Instead, it tends to absorb neutrons without a subsequent fission event, producing neptunium and plutonium. For this reason, reactor fuels must be artificially enriched to contain at least a few percent 235U.

To achieve a self-sustained chain reaction, an average of one neutron emitted in each 235U fission must be captured by another 235U nucleus and cause that nucleus to undergo fission. A useful parameter for describing the level of reactor operation is the reproduction constant $K$, defined as the average number of neutrons from each fission event that cause another fission event. As we have seen, $K$ has an average value of 2.5 in the uncontrolled fission of uranium.

A self-sustained and controlled chain reaction is achieved when $K = 1$. When in this condition, the reactor is said to be critical. When $K < 1$, the reactor is subcritical and the reaction dies out. When $K > 1$, the reactor is supercritical and a runaway reaction occurs. In a nuclear reactor used to furnish power to a utility company, it is necessary to maintain a value of $K$ close to 1. If $K$ rises above this value, the rest energy transformed to internal energy in the reaction could melt the reactor.

Several types of reactor systems allow the kinetic energy of fission fragments to be transformed to other types of energy and eventually transferred out of the

---

1Although Fermi’s reactor was the first manufactured nuclear reactor, there is evidence that a natural fission reaction may have sustained itself for perhaps hundreds of thousands of years in a deposit of uranium in Gabon, West Africa. See G. Cowan, “A Natural Fission Reactor,” *Scientific American* 235(5): 36, 1976.
reactor plant by electrical transmission. The most common reactor in use in the United States is the pressurized-water reactor (Fig. 45.5). We shall examine this type because its main parts are common to all reactor designs. Fission events in the uranium fuel elements in the reactor core raise the temperature of the water contained in the primary loop, which is maintained at high pressure to keep the water from boiling. (This water also serves as the moderator to slow down the neutrons released in the fission events with energy of approximately 2 MeV.) The hot water is pumped through a heat exchanger, where the internal energy of the water is transferred by conduction to the water contained in the secondary loop. The hot water in the secondary loop is converted to steam, which does work to drive a turbine–generator system to create electric power. The water in the secondary loop is isolated from the water in the primary loop to avoid contamination of the secondary water and the steam by radioactive nuclei from the reactor core.

In any reactor, a fraction of the neutrons produced in fission leak out of the uranium fuel elements before inducing other fission events. If the fraction leaking out is too large, the reactor will not operate. The percentage lost is large if the fuel elements are very small because leakage is a function of the ratio of surface area to volume. Therefore, a critical feature of the reactor design is an optimal surface area–to–volume ratio of the fuel elements.

**Control of Power Level**

Safety is of critical importance in the operation of a nuclear reactor. The reproduction constant $K$ must not be allowed to rise above 1, lest a runaway reaction occur. Consequently, reactor design must include a means of controlling the value of $K$.

The basic design of a nuclear reactor core is shown in Figure 45.6. The fuel elements consist of uranium that has been enriched in the $^{235}\text{U}$ isotope. To control the power level, control rods are inserted into the reactor core. These rods are made of materials such as cadmium that are very efficient in absorbing neutrons. By adjusting the number and position of the control rods in the reactor core, the $K$ value
can be varied and any power level within the design range of the reactor can be achieved.

Quick Quiz 45.3 To reduce the value of the reproduction constant $K$, do you
(a) push the control rods deeper into the core or (b) pull the control rods farther out of the core?

Safety and Waste Disposal

The 1986 accident at the Chernobyl reactor in Ukraine and the 2011 nuclear disaster caused by the earthquake and tsunami in Japan rightfully focused attention on reactor safety. Unfortunately, at Chernobyl the activity of the materials released immediately after the accident totaled approximately $1.2 \times 10^{19}$ Bq and resulted in the evacuation of 135,000 people. Thirty individuals died during the accident or shortly thereafter, and data from the Ukraine Radiological Institute suggest that more than 2,500 deaths could be attributed to the Chernobyl accident. In the period 1986–1997, there was a tenfold increase in the number of children contracting thyroid cancer from the ingestion of radioactive iodine in milk from cows that ate contaminated grass. One conclusion of an international conference studying the Ukraine accident was that the main causes of the Chernobyl accident were the coincidence of severe deficiencies in the reactor physical design and a violation of safety procedures. Most of these deficiencies have since been addressed at plants of similar design in Russia and neighboring countries of the former Soviet Union.

The March 2011 accident in Japan was caused by an unfortunate combination of a massive earthquake and subsequent tsunami. The most hard-hit power plant, Fukushima I, shut down automatically after the earthquake. Shutting down a nuclear power plant, however, is not an instantaneous process. Cooling water must continue to be circulated to carry the energy generated by beta decay of the fission by-products out of the reactor core. Unfortunately, the water from the tsunami broke the connection to the power grid, leaving the plant without outside electrical support for circulating the water. While the plant had emergency generators to take over in such a situation, the tsunami inundated the generator rooms, making the generators inoperable. Three of the six reactors at Fukushima experienced meltdown, and there were several explosions. Significant radiation was released into the environment. At the time of this printing, all 54 of Japan’s nuclear power plants have been taken offline, and the Japanese public has expressed strong reluctance to continue with nuclear power.

Commercial reactors achieve safety through careful design and rigid operating protocol, and only when these variables are compromised do reactors pose a danger. Radiation exposure and the potential health risks associated with such exposure are controlled by three layers of containment. The fuel and radioactive fission products are contained inside the reactor vessel. Should this vessel rupture, the reactor building acts as a second containment structure to prevent radioactive material from contaminating the environment. Finally, the reactor facilities must be in a remote location to protect the general public from exposure should radiation escape the reactor building.

A continuing concern about nuclear fission reactors is the safe disposal of radioactive material when the reactor core is replaced. This waste material contains long-lived, highly radioactive isotopes and must be stored over long time intervals in such a way that there is no chance of environmental contamination. At present, sealing radioactive wastes in waterproof containers and burying them in deep geologic repositories seems to be the most promising solution.

Transport of reactor fuel and reactor wastes poses additional safety risks. Accidents during transport of nuclear fuel could expose the public to harmful levels of radiation. The U.S. Department of Energy requires stringent crash tests of all con-
Containers used to transport nuclear materials. Container manufacturers must demonstrate that their containers will not rupture even in high-speed collisions.

Despite these risks, there are advantages to the use of nuclear power to be weighed against the risks. For example, nuclear power plants do not produce air pollution and greenhouse gases as do fossil fuel plants, and the supply of uranium on the Earth is predicted to last longer than the supply of fossil fuels. For each source of energy—whether nuclear, hydroelectric, fossil fuel, wind, solar, or other—the risks must be weighed against the benefits and the availability of the energy source.

45.4 Nuclear Fusion

In Chapter 44, we found that the binding energy for light nuclei \((A < 20)\) is much smaller than the binding energy for heavier nuclei, which suggests a process that is the reverse of fission. As mentioned in Section 39.8, when two light nuclei combine to form a heavier nucleus, the process is called nuclear fusion. Because the mass of the final nucleus is less than the combined masses of the original nuclei, there is a loss of mass accompanied by a release of energy.

Two examples of such energy-liberating fusion reactions are as follows:

\[
\begin{align*}
\frac{1}{1}H + \frac{1}{1}H & \rightarrow \frac{2}{1}H + e^+ + \nu \\
\frac{1}{1}H + \frac{3}{1}H & \rightarrow \frac{3}{2}He + \gamma
\end{align*}
\]

These reactions occur in the core of a star and are responsible for the outpouring of energy from the star. The second reaction is followed by either hydrogen–helium fusion or helium–helium fusion:

\[
\begin{align*}
\frac{1}{1}H + \frac{3}{2}He & \rightarrow \frac{3}{2}He + e^+ + \nu \\
\frac{3}{2}He + \frac{3}{2}He & \rightarrow \frac{4}{2}He + \frac{1}{1}H + \frac{1}{1}H
\end{align*}
\]

These fusion reactions are the basic reactions in the proton–proton cycle, believed to be one of the basic cycles by which energy is generated in the Sun and other stars that contain an abundance of hydrogen. Most of the energy production takes place in the Sun’s interior, where the temperature is approximately \(1.5 \times 10^7\) K. Because such high temperatures are required to drive these reactions, they are called thermonuclear fusion reactions. All the reactions in the proton–proton cycle are exothermic. An overview of the cycle is that four protons combine to generate an alpha particle, positrons, gamma rays, and neutrinos.

Quick Quiz 45.4 In the core of a star, hydrogen nuclei combine in fusion reactions. Once the hydrogen has been exhausted, fusion of helium nuclei can occur. If the star is sufficiently massive, fusion of heavier and heavier nuclei can occur once the helium is used up. Consider a fusion reaction involving two nuclei with the same value of \(A\). For this reaction to be exothermic, which of the following values of \(A\) are impossible? (a) 12 (b) 20 (c) 28 (d) 64

Example 45.2 Energy Released in Fusion

Find the total energy released in the fusion reactions in the proton–proton cycle.

Solution

Conceptualize The net nuclear result of the proton–proton cycle is to fuse four protons to form an alpha particle. Study the reactions above for the proton–proton cycle to be sure you understand how four protons become an alpha particle.

Categorize We use concepts discussed in this section, so we categorize this example as a substitution problem.
Chapter 45  Applications of Nuclear Physics

Terrestrial Fusion Reactions

The enormous amount of energy released in fusion reactions suggests the possibility of harnessing this energy for useful purposes. A great deal of effort is currently under way to develop a sustained and controllable thermonuclear reactor, a fusion power reactor. Controlled fusion is often called the ultimate energy source because of the availability of its fuel source: water. For example, if deuterium were used as the fuel, 0.12 g of it could be extracted from 1 gal of water at a cost of about four cents. This amount of deuterium would release approximately $10^{10}$ J if all nuclei underwent fusion. By comparison, 1 gal of gasoline releases approximately $10^8$ J upon burning and costs far more than four cents.

An additional advantage of fusion reactors is that comparatively few radioactive by-products are formed. For the proton–proton cycle, for instance, the end product is safe, nonradioactive helium. Unfortunately, a thermonuclear reactor that can deliver a net power output spread over a reasonable time interval is not yet a reality, and many difficulties must be resolved before a successful device is constructed.

The Sun’s energy is based in part on a set of reactions in which hydrogen is converted to helium. The proton–proton interaction is not suitable for use in a fusion reactor, however, because the event requires very high temperatures and densities. The process works in the Sun only because of the extremely high density of protons in the Sun’s interior.

The reactions that appear most promising for a fusion power reactor involve deuterium ($^2\text{H}$) and tritium ($^3\text{H}$):

$$ ^2\text{H} + ^2\text{H} \rightarrow ^3\text{He} + ^1\text{n} \quad Q = 3.27 \text{ MeV} $$

$$ ^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + ^1\text{H} \quad Q = 4.03 \text{ MeV} $$

(45.4)

As noted earlier, deuterium is available in almost unlimited quantities from our lakes and oceans and is very inexpensive to extract. Tritium, however, is radioactive ($T_{1/2} = 12.3 \text{ yr}$) and undergoes beta decay to $^3\text{He}$. For this reason, tritium does not occur naturally to any great extent and must be artificially produced.

One major problem in obtaining energy from nuclear fusion is that the Coulomb repulsive force between two nuclei, which carry positive charges, must be overcome before they can fuse. Figure 45.7 is a graph of potential energy as a function of the separation distance between two deuterons (deuteron nuclei, each having charge $+e$). The potential energy is positive in the region $r > R$, where the Coulomb repulsive force dominates ($R \approx 1 \text{ fm}$), and negative in the region $r < R$, where the nuclear force dominates. The fundamental problem then is to give the two nuclei enough kinetic energy to overcome this repulsive force. This requirement can be accomplished by raising the fuel to extremely high temperatures (to approximately $10^8 \text{ K}$). At these high temperatures, the atoms are ionized and the system consists of a collection of electrons and nuclei, commonly referred to as a plasma.

---

**Figure 45.7** Potential energy as a function of separation distance between two deuterons. $R$ is on the order of 1 fm. If we neglect tunneling, the two deuterons require an energy $E$ greater than the height of the barrier to undergo fusion.
Example 45.3  The Fusion of Two Deuterons

For the nuclear force to overcome the repulsive Coulomb force, the separation distance between two deuterons must be approximately \(1.0 \times 10^{-14}\) m.

(A) Calculate the height of the potential barrier due to the repulsive force.

SOLUTION

Conceptualize  Imagine moving two deuterons toward each other. As they move closer together, the Coulomb repulsion force becomes stronger. Work must be done on the system to push against this force, and this work appears in the system of two deuterons as electric potential energy.

Categorize  We categorize this problem as one involving the electric potential energy of a system of two charged particles.

Analyze  Evaluate the potential energy associated with two charges separated by a distance \(r\) (Eq. 25.13) for two deuterons:

\[
U = k \frac{q_1 q_2}{r} = k \left( \frac{e^2}{r} \right) = \left( 8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2 \right) \left( \frac{1.60 \times 10^{-19} \text{ C}^2}{1.0 \times 10^{-11} \text{ m}} \right) \]

\[= 2.3 \times 10^{-14} \text{ J} = \text{0.14 MeV} \]

(B) Estimate the temperature required for a deuteron to overcome the potential barrier, assuming an energy of \(\frac{3}{2} k_B T\) per deuteron (where \(k_B\) is Boltzmann’s constant).

SOLUTION

Because the total Coulomb energy of the pair is 0.14 MeV, the Coulomb energy per deuteron is equal to 0.07 MeV = \(1.1 \times 10^{-11}\) J.

Set this energy equal to the average energy per deuteron:

\[
\frac{3}{2} k_B T = 1.1 \times 10^{-11} \text{ J}
\]

Solve for \(T\):

\[T = \frac{2(1.1 \times 10^{-11} \text{ J})}{3(1.38 \times 10^{-23} \text{ J/K})} = 5.6 \times 10^8 \text{ K} \]

(C) Find the energy released in the deuterium–deuterium reaction

\[
\frac{2}{3} \text{H} + \frac{2}{3} \text{H} \rightarrow \frac{4}{3} \text{H} + \frac{1}{3} \text{n}
\]

SOLUTION

The mass of a single deuterium atom is equal to 2.014 102 u. Therefore, the total mass of the system before the reaction is 4.028 204 u.

Find the sum of the masses after the reaction:

\[3.016 \ 049 \ 049 \text{ u} + 1.007 \ 825 \ 666 \text{ u} = 4.023 \ 874 \ 715 \text{ u} \]

Find the change in mass and convert to energy units:

\[4.028 \ 204 \ 204 \text{ u} - 4.023 \ 874 \ 715 \text{ u} = 0.004 \ 33 \text{ u} \]

\[0.004 \ 33 \text{ u} \times 931.494 \text{ MeV/u} = 4.03 \text{ MeV} \]

Finalize  The calculated temperature in part (B) is too high because the particles in the plasma have a Maxwellian speed distribution (Section 21.5) and therefore some fusion reactions are caused by particles in the high-energy tail of this distribution. Furthermore, even those particles that do not have enough energy to overcome the barrier have some probability of tunneling through (Section 41.5). When these effects are taken into account, a temperature of “only” \(4 \times 10^8 \text{ K}\) appears adequate to fuse two deuterons in a plasma. In part (C), notice that the energy value is consistent with that already given in Equation 45.4.

WHAT IF?  Suppose the tritium resulting from the reaction in part (C) reacts with another deuterium in the reaction

\[
\frac{2}{3} \text{H} + \frac{2}{3} \text{H} \rightarrow \frac{4}{3} \text{He} + \frac{1}{3} \text{n}
\]

How much energy is released in the sequence of two reactions?  

continued
The temperature at which the power generation rate in any fusion reaction exceeds the loss rate is called the critical ignition temperature $T_{\text{ignit}}$. This temperature for the deuterium–deuterium (D–D) reaction is $4 \times 10^8$ K. From the relationship $E < \frac{3}{2} k_B T$, the ignition temperature is equivalent to approximately 52 keV. The critical ignition temperature for the deuterium–tritium (D–T) reaction is approximately $4.5 \times 10^7$ K, or only 6 keV. A plot of the power $P_{\text{gen}}$ generated by fusion versus temperature for the two reactions is shown in Figure 45.8. The straight green line represents the power $P_{\text{lost}}$ lost via the radiation mechanism known as bremsstrahlung (Section 42.8). In this principal mechanism of energy loss, radiation (primarily x-rays) is emitted as the result of electron–ion collisions within the plasma. The intersections of the $P_{\text{lost}}$ line with the $P_{\text{gen}}$ curves give the critical ignition temperatures.

In addition to the high-temperature requirements, two other critical parameters determine whether or not a thermonuclear reactor is successful: the ion density $n$ and confinement time $t$, which is the time interval during which energy injected into the plasma remains within the plasma. British physicist J. D. Lawson (1923–2008) showed that both the ion density and confinement time must be large enough to ensure that more fusion energy is released than the amount required to raise the temperature of the plasma. For a given value of $n$, the probability of fusion between two particles increases as $t$ increases. For a given value of $t$, the collision rate between nuclei increases as $n$ increases. The product $nt$ is referred to as the Lawson number of a reaction. A graph of the value of $nt$ necessary to achieve a net energy output for the D–T and D–D reactions at different temperatures is shown in Figure 45.9. In particular, Lawson’s criterion states that a net energy output is possible for values of $nt$ that meet the following conditions:

$$nt \geq 10^{14} \text{ s/cm}^3 \quad (\text{D–T})$$

$$nt \geq 10^{16} \text{ s/cm}^3 \quad (\text{D–D})$$

These values represent the minima of the curves in Figure 45.9.
Lawson’s criterion was arrived at by comparing the energy required to raise the temperature of a given plasma with the energy generated by the fusion process. The energy $E_{\text{in}}$ required to raise the temperature of the plasma is proportional to the ion density $n$, which we can express as $E_{\text{in}} = C_1 n$, where $C_1$ is some constant. The energy generated by the fusion process is proportional to $n^2 \tau$, or $E_{\text{gen}} = C_2 n^2 \tau$. This dependence may be understood by realizing that the fusion energy released is proportional to both the rate at which interacting ions collide ($\propto n^2$) and the confinement time $\tau$. Net energy is produced when $E_{\text{gen}} > E_{\text{in}}$. When the constants $C_1$ and $C_2$ are calculated for different reactions, the condition that $E_{\text{gen}} \geq E_{\text{in}}$ leads to Lawson’s criterion.

Current efforts are aimed at meeting Lawson’s criterion at temperatures exceeding $T_{\text{ign}}$. Although the minimum required plasma densities have been achieved, the problem of confinement time is more difficult. The two basic techniques under investigation for solving this problem are magnetic confinement and inertial confinement.

Magnetic Confinement

Many fusion-related plasma experiments use magnetic confinement to contain the plasma. A toroidal device called a tokamak, first developed in Russia, is shown in Figure 45.10a. A combination of two magnetic fields is used to confine and stabilize the plasma: (1) a strong toroidal field produced by the current in the toroidal windings surrounding a doughnut-shaped vacuum chamber and (2) a weaker “poloidal” field produced by the toroidal current. In addition to confining the plasma, the toroidal current is used to raise its temperature. The resultant helical magnetic field lines spiral around the plasma and keep it from touching the walls of the vacuum chamber. (If the plasma touches the walls, its temperature is reduced and heavy impurities sputtered from the walls “poison” it, leading to large power losses.)

One major breakthrough in magnetic confinement in the 1980s was in the area of auxiliary energy input to reach ignition temperatures. Experiments have shown

---

Lawson’s criterion neglects the energy needed to set up the strong magnetic field used to confine the hot plasma in a magnetic confinement approach. This energy is expected to be about 20 times greater than the energy required to raise the temperature of the plasma. It is therefore necessary either to have a magnetic energy recovery system or to use superconducting magnets.
that injecting a beam of energetic neutral particles into the plasma is a very efficient method of raising it to ignition temperatures. Radio-frequency energy input will probably be needed for reactor-size plasmas.

When it was in operation from 1982 to 1997, the Tokamak Fusion Test Reactor (TFTR, Fig. 45.10b) at Princeton University reported central ion temperatures of 510 million degrees Celsius, more than 30 times greater than the temperature at the center of the Sun. The \( n\tau \) values in the TFTR for the D–T reaction were well above \( 10^{13} \) s/cm\(^3\) and close to the value required by Lawson's criterion. In 1991, reaction rates of \( 6 \times 10^{17} \) D–T fusions per second were reached in the Joint European Torus (JET) tokamak at Abington, England.

One of the new generation of fusion experiments is the National Spherical Torus Experiment (NSTX) at the Princeton Plasma Physics Laboratory and shown in Figure 45.10c. This reactor was brought on line in February 1999 and has been running fusion experiments since then. Rather than the doughnut-shaped plasma of a tokamak, the NSTX produces a spherical plasma that has a hole through its center. The major advantage of the spherical configuration is its ability to confine the plasma at a higher pressure in a given magnetic field. This approach could lead to development of smaller, more economical fusion reactors.

An international collaborative effort involving the United States, the European Union, Japan, China, South Korea, India, and Russia is currently under way to build a fusion reactor called ITER. This acronym stands for International Thermonuclear Experimental Reactor, although recently the emphasis has shifted to interpreting “iter” in terms of its Latin meaning, “the way.” One reason proposed for this change is to avoid public misunderstanding and negative connotations toward the word thermonuclear. This facility will address the remaining technological and scientific issues concerning the feasibility of fusion power. The design is completed, and Cadarache, France, was chosen in June 2005 as the reactor site. Construction began in 2007 and will require about 10 years, with fusion operation projected to begin in 2019. If the planned device works as expected, the Lawson number for ITER will be about six times greater than the current record holder, the JT-60U tokamak in Japan. ITER is expected to produce ten times as much output power as input power, and the energy content of the alpha particles inside the reactor will be so intense that they will sustain the fusion reaction, allowing the auxiliary energy sources to be turned off once the reaction is initiated.

**Example 45.4  Inside a Fusion Reactor**

In 1998, the JT-60U tokamak in Japan operated with a D–T plasma density of \( 4.8 \times 10^{15} \) cm\(^{-3}\) at a temperature (in energy units) of 24.1 keV. It confined this plasma inside a magnetic field for 1.1 s.

**(A)** Do these data meet Lawson's criterion?

**Solution**

**Conceptualize** With the help of the third of Equations 45.4, imagine many such reactions occurring in a plasma of high temperature and high density.

**Categorize** We use the concept of the Lawson number discussed in this section, so we categorize this example as a substitution problem.

Evaluate the Lawson number for the JT-60U:

\[
 n\tau = (4.8 \times 10^{15} \text{ cm}^{-3})(1.1 \text{ s}) = 5.3 \times 10^{15} \text{ s/cm}^3
\]

This value is close to meeting Lawson's criterion of \( 10^{14} \) s/cm\(^3\) for a D–T plasma given in Equation 45.5. In fact, scientists recorded a power gain of 1.25, indicating that the reactor operated slightly past the break-even point and produced more energy than it required to maintain the plasma.

**(B)** How does the plasma density compare with the density of atoms in an ideal gas when the gas is under standard conditions \( (T = 0^\circ\text{C} \text{ and } P = 1 \text{ atm}) \)?
Inertial Confinement

The second technique for confining a plasma, called inertial confinement, makes use of a D–T target that has a very high particle density. In this scheme, the confinement time is very short (typically $10^{-11}$ to $10^{-9}$ s), and, because of their own inertia, the particles do not have a chance to move appreciably from their initial positions. Therefore, Lawson’s criterion can be satisfied by combining a high particle density with a short confinement time.

Laser fusion is the most common form of inertial confinement. A small D–T pellet, approximately 1 mm in diameter, is struck simultaneously by several focused, high-intensity laser beams, resulting in a large pulse of input energy that causes the surface of the fuel pellet to evaporate (Fig. 45.11). The escaping particles exert a third-law reaction force on the core of the pellet, resulting in a strong, inwardly moving compressive shock wave. This shock wave increases the pressure and density of the core and produces a corresponding increase in temperature. When the temperature of the core reaches ignition temperature, fusion reactions occur.

One of the leading laser fusion laboratories in the United States is the Omega facility at the University of Rochester in New York. This facility focuses 24 laser beams on the target. Currently under operation at the Lawrence Livermore National Laboratory in Livermore, California, is the National Ignition Facility. The research apparatus there includes 192 laser beams that can be focused on a deuterium–tritium pellet. Construction was completed in early 2009, and a test firing of the lasers in March 2012 broke the record for lasers, delivering 1.87 MJ to a target. This energy is delivered in such a short time interval that the power is immense: 500 trillion watts, more than 1 000 times the power used in the United States at any moment.

Fusion Reactor Design

In the D–T fusion reaction

$$\frac{2}{3}H + \frac{1}{3}H \rightarrow \frac{3}{2}He + \frac{1}{0}n \quad Q = 17.59 \text{ MeV}$$

the alpha particle carries 20% of the energy and the neutron carries 80%, or approximately 14 MeV. A diagram of the deuterium–tritium fusion reaction is shown in Figure 45.12. Because the alpha particles are charged, they are primarily absorbed by the plasma, causing the plasma’s temperature to increase. In contrast, the 14-MeV neutrons, being electrically neutral, pass through the plasma and are absorbed by a surrounding blanket material, where their large kinetic energy is extracted and used to generate electric power.

One scheme is to use molten lithium metal as the neutron-absorbing material and to circulate the lithium in a closed heat-exchange loop, thereby producing steam and driving turbines as in a conventional power plant. Figure 45.13 (page 1432) shows a diagram of such a reactor. It is estimated that a blanket of lithium, approximately 1 m thick will capture nearly 100% of the neutrons from the fusion of a small D–T pellet.

---

**SOLUTION**

Find the density of atoms in a sample of ideal gas by evaluating $N_A/V_{mol}$, where $N_A$ is Avogadro’s number and $V_{mol}$ is the molar volume of an ideal gas under standard conditions, $2.24 \times 10^{-2} \text{ m}^3/\text{mol}$:

\[
\frac{N_A}{V_{mol}} = \frac{6.02 \times 10^{23} \text{ atoms/mol}}{2.24 \times 10^{-2} \text{ m}^3/\text{mol}} = 2.7 \times 10^{25} \text{ atoms/m}^3
\]

This value is more than 500 000 times greater than the plasma density in the reactor.
The capture of neutrons by lithium is described by the reaction
\[ ^1\text{n} + ^7\text{Li} \rightarrow ^3\text{H} + ^4\text{He} \]
where the kinetic energies of the charged tritium $^3\text{H}$ and alpha particle are transformed to internal energy in the molten lithium. An extra advantage of using lithium as the energy-transfer medium is that the tritium produced can be separated from the lithium and returned as fuel to the reactor.

### Advantages and Problems of Fusion

If fusion power can ever be harnessed, it will offer several advantages over fission-generated power: (1) low cost and abundance of fuel (deuterium), (2) impossibility of runaway accidents, and (3) decreased radiation hazard. Some of the anticipated problems and disadvantages include (1) scarcity of lithium, (2) limited supply of helium, which is needed for cooling the superconducting magnets used to produce strong confining fields, and (3) structural damage and induced radioactivity caused by neutron bombardment. If such problems and the engineering design factors can be resolved, nuclear fusion may become a feasible source of energy in the twenty-first century.

### 45.5 Radiation Damage

In Chapter 34, we learned that electromagnetic radiation is all around us in the form of radio waves, microwaves, light waves, and so on. In this section, we describe forms of radiation that can cause severe damage as they pass through matter, such as radiation resulting from radioactive processes and radiation in the form of energetic particles such as neutrons and protons.

The degree and type of damage depend on several factors, including the type and energy of the radiation and the properties of the matter. The metals used in nuclear reactor structures can be severely weakened by high fluxes of energetic neutrons because these high fluxes often lead to metal fatigue. The damage in such situations is in the form of atomic displacements, often resulting in major alterations in the properties of the material.
Radiation damage in biological organisms is primarily due to ionization effects in cells. A cell’s normal operation may be disrupted when highly reactive ions are formed as the result of ionizing radiation. For example, hydrogen and the hydroxyl radical OH\(^{−}\) produced from water molecules can induce chemical reactions that may break bonds in proteins and other vital molecules. Furthermore, the ionizing radiation may affect vital molecules directly by removing electrons from their structure. Large doses of radiation are especially dangerous because damage to a great number of molecules in a cell may cause the cell to die. Although the death of a single cell is usually not a problem, the death of many cells may result in irreversible damage to the organism. Cells that divide rapidly, such as those of the digestive tract, reproductive organs, and hair follicles, are especially susceptible. In addition, cells that survive the radiation may become defective. These defective cells can produce more defective cells and can lead to cancer.

In biological systems, it is common to separate radiation damage into two categories: somatic damage and genetic damage. Somatic damage is that associated with any body cell except the reproductive cells. Somatic damage can lead to cancer or can seriously alter the characteristics of specific organisms. Genetic damage affects only reproductive cells. Damage to the genes in reproductive cells can lead to defective offspring. It is important to be aware of the effect of diagnostic treatments, such as x-rays and other forms of radiation exposure, and to balance the significant benefits of treatment with the damaging effects.

Damage caused by radiation also depends on the radiation’s penetrating power. Alpha particles cause extensive damage, but penetrate only to a shallow depth in a material due to the strong interaction with other charged particles. Neutrons do not interact via the electric force and hence penetrate deeper, causing significant damage. Gamma rays are high-energy photons that can cause severe damage, but often pass through matter without interaction.

Several units have been used historically to quantify the amount, or dose, of any radiation that interacts with a substance.

The roentgen (R) is that amount of ionizing radiation that produces an electric charge of \(3.33 \times 10^{-10}\) C in 1 cm\(^3\) of air under standard conditions.

Equivalently, the roentgen is that amount of radiation that increases the energy of 1 kg of air by \(8.76 \times 10^{-3}\) J.

For most applications, the roentgen has been replaced by the rad (an acronym for radiation absorbed dose):

One rad is that amount of radiation that increases the energy of 1 kg of absorbing material by \(1 \times 10^{-2}\) J.

Although the rad is a perfectly good physical unit, it is not the best unit for measuring the degree of biological damage produced by radiation because damage depends not only on the dose but also on the type of the radiation. For example, a given dose of alpha particles causes about ten times more biological damage than an equal dose of x-rays. The RBE (relative biological effectiveness) factor for a given type of radiation is the number of rads of x-radiation or gamma radiation that produces the same biological damage as 1 rad of the radiation being used. The RBE factors for different types of radiation are given in Table 45.1 (page 1434). The values are only approximate because they vary with particle energy and with the form of the damage. The RBE factor should be considered only a first-approximation guide to the actual effects of radiation.

Finally, the rem (radiation equivalent in man) is the product of the dose in rad and the RBE factor:

\[
\text{Dose in rem} = \text{dose in rad} \times \text{RBE}
\]
According to this definition, 1 rem of any two types of radiation produces the same amount of biological damage. Table 45.1 shows that a dose of 1 rad of fast neutrons represents an effective dose of 10 rem, but 1 rad of gamma radiation is equivalent to a dose of only 1 rem.

This discussion has focused on measurements of radiation dosage in units such as rads and rems because these units are still widely used. They have, however, been formally replaced with new SI units. The rad has been replaced with the gray (Gy), equal to 100 rad, and the rem has been replaced with the sievert (Sv), equal to 100 rem. Table 45.2 summarizes the older and the current SI units of radiation dosage.

Low-level radiation from natural sources such as cosmic rays and radioactive rocks and soil delivers to each of us a dose of approximately 2.4 mSv/yr. This radiation, called background radiation, varies with geography, with the main factors being altitude (exposure to cosmic rays) and geology (radon gas released by some rock formations, deposits of naturally radioactive minerals).

The upper limit of radiation dose rate recommended by the U.S. government (apart from background radiation) is approximately 5 mSv/yr. Many occupations involve much higher radiation exposures, so an upper limit of 50 mSv/yr has been set for combined whole-body exposure. Higher upper limits are permissible for certain parts of the body, such as the hands and the forearms. A dose of 4 to 5 Sv results in a mortality rate of approximately 50% (which means that half the people exposed to this radiation level die). The most dangerous form of exposure for most people is either ingestion or inhalation of radioactive isotopes, especially isotopes of those elements the body retains and concentrates, such as $^{90}$Sr.

### 45.6 Uses of Radiation

Nuclear physics applications are extremely widespread in manufacturing, medicine, and biology. In this section, we present a few of these applications and the underlying theories supporting them.

#### Tracing

Radioactive tracers are used to track chemicals participating in various reactions. One of the most valuable uses of radioactive tracers is in medicine. For example, iodine, a nutrient needed by the human body, is obtained largely through the
intake of iodized salt and seafood. To evaluate the performance of the thyroid, the patient drinks a very small amount of radioactive sodium iodide containing $^{131}$I, an artificially produced isotope of iodine (the natural, nonradioactive isotope is $^{127}$I). The amount of iodine in the thyroid gland is determined as a function of time by measuring the radiation intensity at the neck area. How much of the isotope $^{131}$I remains in the thyroid is a measure of how well that gland is functioning.

A second medical application is indicated in Figure 45.14. A solution containing radioactive sodium is injected into a vein in the leg, and the time at which the radioisotope arrives at another part of the body is detected with a radiation counter. The elapsed time is a good indication of the presence or absence of constrictions in the circulatory system.

Tracers are also useful in agricultural research. Suppose the best method of fertilizing a plant is to be determined. A certain element in a fertilizer, such as nitrogen, can be tagged (identified) with one of its radioactive isotopes. The fertilizer is then sprayed on one group of plants, sprinkled on the ground for a second group, and raked into the soil for a third. A Geiger counter is then used to track the nitrogen through each of the three groups.

Tracing techniques are as wide ranging as human ingenuity can devise. Today, applications range from checking how teeth absorb fluoride to monitoring how cleansers contaminate food-processing equipment to studying deterioration inside an automobile engine. In this last case, a radioactive material is used in the manufacture of the car’s piston rings and the oil is checked for radioactivity to determine the amount of wear on the rings.

**Materials Analysis**

For centuries, a standard method of identifying the elements in a sample of material has been chemical analysis, which involves determining how the material reacts with various chemicals. A second method is spectral analysis, which works because each element, when excited, emits its own characteristic set of electromagnetic wavelengths. These methods are now supplemented by a third technique, *neutron activation analysis*. A disadvantage of both chemical and spectral methods is that a fairly large sample of the material must be destroyed for the analysis. In addition, extremely small quantities of an element may go undetected by either method. Neutron activation analysis has an advantage over chemical analysis and spectral analysis in both respects.

When a material is irradiated with neutrons, nuclei in the material absorb the neutrons and are changed to different isotopes, most of which are radioactive. For example, $^{64}$Cu absorbs a neutron to become $^{65}$Cu, which undergoes beta decay:

$$^{64}\text{Cu} + \text{n} \rightarrow ^{65}\text{Cu} \rightarrow ^{65}\text{Zn} + e^- + \nu$$
The presence of the copper can be deduced because it is known that $^{64}\text{Cu}$ has a half-life of 5.1 min and decays with the emission of beta particles having a maximum energy of 2.63 MeV. Also emitted in the decay of $^{64}\text{Cu}$ is a 1.04-MeV gamma ray. By examining the radiation emitted by a substance after it has been exposed to neutron irradiation, one can detect extremely small amounts of an element in that substance.

Neutron activation analysis is used routinely in a number of industries. In commercial aviation, for example, it is used to check airline luggage for hidden explosives. One nonroutine use is of historical interest. Napoleon died on the island of St. Helena in 1821, supposedly of natural causes. Over the years, suspicion has existed that his death was not all that natural. After his death, his head was shaved and locks of his hair were sold as souvenirs. In 1961, the amount of arsenic in a sample of this hair was measured by neutron activation analysis, and an unusually large quantity of arsenic was found. (Activation analysis is so sensitive that very small pieces of a single hair could be analyzed.) Results showed that the arsenic was fed to him irregularly. In fact, the arsenic concentration pattern corresponded to the fluctuations in the severity of Napoleon’s illness as determined from historical records.

Art historians use neutron activation analysis to detect forgeries. The pigments used in paints have changed throughout history, and old and new pigments react differently to neutron activation. The method can even reveal hidden works of art behind existing paintings because an older, hidden layer of paint reacts differently than the surface layer to neutron activation.

Radiation Therapy

Radiation causes much damage to rapidly dividing cells. Therefore, it is useful in cancer treatment because tumor cells divide extremely rapidly. Several mechanisms can be used to deliver radiation to a tumor. In Section 42.8, we discussed the use of high-energy x-rays in the treatment of cancerous tissue. Other treatment protocols include the use of narrow beams of radiation from a radioactive source. As an example, Figure 45.15 shows a machine that uses $^{60}\text{Co}$ as a source. The $^{60}\text{Co}$ isotope emits gamma rays with photon energies higher than 1 MeV.

In other situations, a technique called brachytherapy is used. In this treatment plan, thin radioactive needles called seeds are implanted in the cancerous tissue. The energy emitted from the seeds is delivered directly to the tumor, reducing the exposure of surrounding tissue to radiation damage. In the case of prostate cancer, the active isotopes used in brachytherapy include $^{125}\text{I}$ and $^{103}\text{Pd}$.

Food Preservation

Radiation is finding increasing use as a means of preserving food because exposure to high levels of radiation can destroy or incapacitate bacteria and mold spores (Fig. 45.16). Techniques include exposing foods to gamma rays, high-energy electron beams, and x-rays. Food preserved by such exposure can be placed in a sealed container (to keep out new spoiling agents) and stored for long periods of time. There is little or no evidence of adverse effect on the taste or nutritional value of food.

Figure 45.15 This large machine is being set to deliver a dose of radiation from $^{60}\text{Co}$ in an effort to destroy a cancerous tumor. Cancer cells are especially susceptible to this type of therapy because they tend to divide more often than cells of healthy tissue nearby.
from irradiation. The safety of irradiated foods has been endorsed by the World Health Organization, the Centers for Disease Control and Prevention, the U.S. Department of Agriculture, and the Food and Drug Administration. Irradiation of food is presently permitted in more than 50 countries. Some estimates place the amount of irradiated food in the world as high as 500 000 metric tons each year.

**Figure 45.16** The strawberries on the left are untreated and have become moldy. The unspoiled strawberries on the right have been irradiated. The radiation has killed or incapacitated the mold spores that have spoiled the strawberries on the left.

---

**Summary**

**Concepts and Principles**

- The probability that neutrons are captured as they move through matter generally increases with decreasing neutron energy. A thermal neutron is a slow-moving neutron that has a high probability of being captured by a nucleus in a neutron capture event:

\[
^{1}n + ^{A}X \rightarrow ^{A+1}X^{*} \rightarrow ^{A+1}X + \gamma
\]

where \(^{A+1}X^{*}\) is an excited intermediate nucleus that rapidly emits a photon.

- **Nuclear fission** occurs when a very heavy nucleus, such as \(^{235}\text{U}\), splits into two smaller fission fragments. Thermal neutrons can create fission in \(^{235}\text{U}\):

\[
^{1}n + ^{235}\text{U} \rightarrow ^{236}\text{U}^{*} \rightarrow X + Y + \text{neutrons}
\]

where \(^{236}\text{U}^{*}\) is an intermediate excited state and X and Y are the fission fragments. On average, 2.5 neutrons are released per fission event. The fragments then undergo a series of beta and gamma decays to various stable isotopes. The energy released per fission event is approximately 200 MeV.

- In **nuclear fusion**, two light nuclei fuse to form a heavier nucleus and release energy. The major obstacle in obtaining useful energy from fusion is the large Coulomb repulsive force between the charged nuclei at small separation distances. The temperature required to produce fusion is on the order of \(10^{9}\) K, and at this temperature, all matter occurs as a plasma.

- In a fusion reactor, the plasma temperature must reach the **critical ignition temperature**, the temperature at which the power generated by the fusion reactions exceeds the power lost in the system. The most promising fusion reaction is the D–T reaction, which has a critical ignition temperature of approximately \(4.5 \times 10^{7}\) K. Two critical parameters in fusion reactor design are **ion density** \(n\) and **confinement time** \(\tau\), the time interval during which the interacting particles must be maintained at \(T > T_{\text{ign}}\). **Lawson’s criterion** states that for the D–T reaction, \(n\tau \geq 10^{14} \text{s/cm}^3\).
1. In a certain fission reaction, a $^{235}\text{U}$ nucleus captures a neutron. This process results in the creation of the products $^{137}\text{I}$ and $^{96}\text{Y}$ along with how many neutrons? (a) 1 (b) 2 (c) 3 (d) 4 (e) 5

2. Which particle is most likely to be captured by a $^{235}\text{U}$ nucleus and cause it to undergo fission? (a) an energetic proton (b) an energetic neutron (c) a slow-moving alpha particle (d) a slow-moving neutron (e) a fast-moving electron

3. In the first nuclear weapon test carried out in New Mexico, the energy released was equivalent to approximately 17 kilotons of TNT. Estimate the mass decrease in the nuclear fuel representing the energy converted from rest energy into other forms in this event. Note: One ton of TNT has the energy equivalent of $4.2 \times 10^9$ J. (a) 1 $\mu$g (b) 1 mg (c) 1 g (d) 1 kg (e) 20 kg

4. Working with radioactive materials at a laboratory over one year, (a) Tom received 1 rem of alpha radiation, (b) Karen received 1 rad of fast neutrons, (c) Paul received 1 rad of thermal neutrons as a whole-body dose, and (d) Ingrid received 1 rad of thermal neutrons to her hands only. Rank these four doses according to the likely amount of biological damage from the greatest to the least, noting any cases of equality.

5. If the moderator were suddenly removed from a nuclear reactor in an electric generating station, what is the most likely consequence? (a) The reactor would go supercritical, and a runaway reaction would occur. (b) The nuclear reaction would proceed in the same way, but the reactor would overheat. (c) The reactor would become subcritical, and the reaction would die out. (d) No change would occur in the reactor’s operation.

6. You may use Figure 44.5 to answer this question. Three nuclear reactions take place, each involving 108 nucleons: (1) eighteen $^6\text{Li}$ nuclei fuse in pairs to form nine $^{12}\text{C}$ nuclei, (2) four nuclei each with 27 nucleons fuse in pairs to form two nuclei with 54 nucleons, and (3) one nucleus with 108 nucleons fissions to form two nuclei with 54 nucleons. Rank these three reactions from the largest positive Q value (representing energy output) to the largest negative value (representing energy input). Also include $Q = 0$ in your ranking to make clear which of the reactions put out energy and which absorb energy. Note any cases of equality in your ranking.

7. A device called a bubble chamber uses a liquid (usually liquid hydrogen) maintained near its boiling point. Ions produced by incoming charged particles from nuclear decays leave bubble tracks, which can be photographed. Figure OQ45.7 shows particle tracks in a bubble chamber immersed in a magnetic field. The tracks are generally spirals rather than sections of circles. What is the primary reason for this shape? (a) The magnetic field is not perpendicular to the velocity of the particles. (b) The magnetic field is not uniform in space. (c) The forces on the particles increase with time. (d) The speeds of the particles decrease with time.

8. If an alpha particle and an electron have the same kinetic energy, which undergoes the greater deflection when passed through a magnetic field? (a) The alpha particle does. (b) The electron does. (c) They undergo the same deflection. (d) Neither is deflected.

9. Which of the following fuel conditions is not necessary to operate a self-sustained controlled fusion reactor? (a) The fuel must be at a sufficiently high temperature. (b) The fuel must be radioactive. (c) The fuel must be confined at a sufficiently high density. (d) The fuel must be confined for a sufficiently long period of time. (e) Conditions (a) through (d) are all necessary.

1. What factors make a terrestrial fusion reaction difficult to achieve?

2. Lawson's criterion states that the product of ion density and confinement time must exceed a certain number before a break-even fusion reaction can occur. Why should these two parameters determine the outcome?

3. Why would a fusion reactor produce less radioactive waste than a fission reactor?

4. Discuss the advantages and disadvantages of fission reactors from the point of view of safety, pollution, and resources. Make a comparison with power generated from the burning of fossil fuels.
9. Why is water a better shield against neutrons than lead or steel?
The atomic masses of the fission products are 97.912 735 u for $^{98}_{40}$Zr and 134.916 450 u for $^{135}_{52}$Te.

10. Seawater contains 3.00 mg of uranium per cubic meter. (a) Given that the average ocean depth is about 4.00 km and water covers two-thirds of the Earth’s surface, estimate the amount of uranium dissolved in the ocean. (b) About 0.700% of naturally occurring uranium is the fissionable isotope $^{235}$U. Estimate how long the uranium in the oceans could supply the world’s energy needs at the current usage of $1.50 \times 10^{13}$ J/s.

11. Review. Suppose seawater exerts an average frictional drag force of $1.00 \times 10^5$ N on a nuclear-powered ship. The fuel consists of enriched uranium containing 3.40% of the fissionable isotope $^{235}$U, and the ship’s reactor has an efficiency of 20.0%. Assuming 200 MeV is released per fission event, how far can the ship travel per kilogram of fuel?

Section 45.3 Nuclear Reactors

12. Assume ordinary soil contains natural uranium in an amount of 1 part per million by mass. (a) How much uranium is in the top 1.00 m of soil on a 1-acre ($43 560$-ft$^2$) plot of ground, assuming the specific gravity of soil is 4.00? (b) How much of the isotope $^{235}$U, appropriate for nuclear reactor fuel, is in this soil? Hint: See Table 44.2 for the percent abundance of $^{235}$U.

13. If the reproduction constant is 1.00 25 for a chain reaction in a fission reactor and the average time interval between successive fissions is 1.20 ms, by what factor does the reaction rate increase in one minute?

14. To minimize neutron leakage from a reactor, the ratio of the surface area to the volume should be a minimum. For a given volume $V$, calculate this ratio for (a) a sphere, (b) a cube, and (c) a parallelepiped of dimensions $a \times a \times 2a$. (d) Which of these shapes would have minimum leakage? Which would have maximum leakage? Explain your answers.

15. The probability of a nuclear reaction increases dramatically when the incident particle is given energy above the “Coulomb barrier,” which is the electric potential energy of the two nuclei when their surfaces barely touch. Compute the Coulomb barrier for the absorption of an alpha particle by a gold nucleus.

16. A large nuclear power reactor produces approximately 3 000 MW of power in its core. Three months after a reactor is shut down, the core power from radioactive by-products is 10.0 MW. Assuming each emission delivers 1.00 MeV of energy to the power, find the activity in becquerels three months after the reactor is shut down.

17. According to one estimate, there are $4.40 \times 10^6$ metric tons of world uranium reserves extractable at $\$130$/kg or less. We wish to determine if these reserves are sufficient to supply all the world’s energy needs. About 0.700% of naturally occurring uranium is the fissionable isotope $^{235}$U. (a) Calculate the mass of $^{235}$U in the reserve in grams. (b) Find the number of moles of $^{235}$U in the reserve. (c) Find the number of $^{235}$U nuclei in the reserve. (d) Assuming 200 MeV is obtained from each fission reaction and all this energy is captured, calculate the total energy in joules that can be extracted from the reserve. (e) Assuming the rate of world power consumption remains constant at $1.50 \times 10^{15}$ J/s, how many years could the uranium reserve provide for all the world’s energy needs? (f) What conclusion can be drawn?

18. Why is the following situation impossible? An engineer working on nuclear power makes a breakthrough so that he is able to control what daughter nuclei are created in a fission reaction. By carefully controlling the process, he is able to restrict the fission reactions to just this single possibility: the uranium-235 nucleus absorbs a slow neutron and splits into lanthanum-141 and bromine-94. Using this breakthrough, he is able to design and build a successful nuclear reactor in which only this single process occurs.

19. An all-electric home uses approximately 2 000 kWh of electric energy per month. How much uranium-235 would be required to provide this house with its energy needs for one year? Assume 100% conversion efficiency and 208 MeV released per fission.

20. A particle cannot generally be localized to distances much smaller than its de Broglie wavelength. This fact can be taken to mean that a slow neutron appears to be larger to a target particle than does a fast neutron in the sense that the slow neutron has probabilities of being found over a larger volume of space. For a thermal neutron at room temperature of 300 K, find (a) the linear momentum and (b) the de Broglie wavelength. (c) State how this effective size compares with both nuclear and atomic dimensions.

Section 45.4 Nuclear Fusion

21. When a star has exhausted its hydrogen fuel, it may fuse other nuclear fuels. At temperatures above $1.00 \times 10^8$ K, helium fusion can occur. Consider the following processes. (a) Two alpha particles fuse to produce a nucleus $A$ and a gamma ray. What is nucleus $A$? (b) Nucleus $A$ from part (a) absorbs an alpha particle to produce nucleus $B$ and a gamma ray. What is nucleus $B$? (c) Find the total energy released in the sequence of reactions given in parts (a) and (b).

22. An all-electric home uses 2 000 kWh of electric energy per month. Assuming all energy released from fusion could be captured, how many fusion events described by the reaction $\text{D} + \text{D} \rightarrow \text{He} + n$ would be required to keep this home running for one year?

23. Find the energy released in the fusion reaction $\text{H} + \text{H} \rightarrow \text{He} + \gamma$
24. Two nuclei having atomic numbers $Z_1$ and $Z_2$ approach each other with a total energy $E$. (a) When they are far apart, they interact only by electric repulsion. If they approach to a distance of $1.00 \times 10^{-14}$ m, the nuclear force suddenly takes over to make them fuse. Find the minimum value of $E$, in terms of $Z_1$ and $Z_2$, required to produce fusion. (b) State how $E$ depends on the atomic numbers. (c) If $Z_1 + Z_2$ is to have a certain target value such as 60, would it be energetically favorable to take $Z_1 = 1$ and $Z_2 = 59$, or $Z_1 = Z_2 = 30$, or some other choice? Explain your answer. (d) Evaluate from your expression the minimum energy for fusion for the D–D and D–T reactions (the first and third reactions in Eq. 45.4).

25. (a) Consider a fusion generator built to create 3.00 GW of power. Determine the rate of fuel burning in grams per hour if the D–T reaction is used. (b) Do the same for the D–D reaction, assuming the reaction products are split evenly between (n, 3He) and (p, 3H).

26. Review. Consider the deuterium–tritium fusion reaction with the tritium nucleus at rest:

$$\text{^2H} + \text{^3H} \rightarrow \text{^4He} + \text{n}$$

(a) Suppose the reactant nuclei will spontaneously fuse if their surfaces touch. From Equation 44.1, determine the required distance of closest approach between their centers. (b) What is the electric potential energy (in electron volts) at this distance? (c) Suppose the deuteron is fired straight at an originally stationary tritium nucleus with just enough energy to reach the required distance of closest approach. What is the common speed of the deuteron and tritium nuclei, in terms of the initial deuteron speed $v_d$, as they touch? (d) Use energy methods to find the minimum initial deuteron energy required to achieve fusion. (e) Why does the fusion reaction actually occur at much lower deuteron energies than the energy calculated in part (d)?

27. Of all the hydrogen in the oceans, 0.030 0% of the mass is deuterium. The oceans have a volume of 317 million m$^3$. (a) If nuclear fusion were controlled and all the deuterium in the oceans were fused to tritium, how many joules of energy would be released? (b) What If? World power consumption is approximately $1.50 \times 10^{13}$ W. If consumption were 100 times greater, how many years would the energy calculated in part (a) last?

28. It has been suggested that fusion reactors are safe from explosion because the plasma never contains enough energy to do much damage. (a) In 1992, the TFTR reactor, with a plasma volume of approximately 50.0 m$^3$, achieved an ion temperature of 4.00 $\times$ $10^8$ K, an ion density of $2.00 \times 10^{13}$ cm$^{-3}$, and a confinement time of 1.40 s. Calculate the amount of energy stored in the plasma of the TFTR reactor. (b) How many kilograms of water at 270°C could be boiled away by this much energy?

**To understand why plasma containment is necessary, consider the rate at which an unconfined plasma would be lost.** (a) Estimate the rms speed of deuterons in a plasma at a temperature of $4.00 \times 10^8$ K. (b) What If? Estimate the order of magnitude of the time interval during which such a plasma would remain in a 10.0-cm cube if no steps were taken to contain it.

30. Another series of nuclear reactions that can produce energy in the interior of stars is the carbon cycle first proposed by Hans Bethe in 1939, leading to his Nobel Prize in Physics in 1967. This cycle is most efficient when the central temperature in a star is above $1.6 \times 10^7$ K. Because the temperature at the center of the Sun is only $1.5 \times 10^7$ K, the following cycle produces less than 10% of the Sun’s energy. (a) A high-energy proton is absorbed by $^{12}$C. Another nucleus, $A$, is produced in the reaction, along with a gamma ray. Identify nucleus $A$. (b) Nucleus $A$ decays through positron emission to form nucleus $B$. Identify nucleus $B$. (c) Nucleus $B$ absorbs a proton to produce nucleus $C$ and a gamma ray. Identify nucleus $C$. (d) Nucleus $C$ absorbs a proton to produce nucleus $D$ and a gamma ray. Identify nucleus $D$. (e) Nucleus $D$ decays through positron emission to produce nucleus $E$. Identify nucleus $E$. (f) Nucleus $E$ absorbs a proton to produce nucleus $F$ plus an alpha particle. Identify nucleus $F$. (g) What is the significance of the final nucleus in the last step of the cycle outlined in part (f)?

31. Review. To confine a stable plasma, the magnetic energy density in the magnetic field (Eq. 32.14) must exceed the pressure $2nk_{B}T$ of the plasma by a factor of at least 10. In this problem, assume a confinement time $\tau = 1.00$ s. (a) Using Lawson’s criterion, determine the ion density required for the D–T reaction. (b) From the ignition-temperature criterion, determine the required plasma pressure. (c) Determine the magnitude of the magnetic field required to contain the plasma.

**Section 45.5 Radiation Damage**

32. Assume an x-ray technician takes an average of eight x-rays per workday and receives a dose of 5.0 rem/yr as a result. (a) Estimate the dose in rem per x-ray taken. (b) Explain how the technician’s exposure compares with low-level background radiation.

33. When gamma rays are incident on matter, the intensity of the gamma rays passing through the material varies with depth $x$ as $I(x) = I_0 e^{-\mu x}$, where $I_0$ is the intensity of the radiation at the surface of the material (at $x = 0$) and $\mu$ is the linear absorption coefficient. For 0.400-MeV gamma rays in lead, the linear absorption coefficient is 1.59 cm$^{-1}$. (a) Determine the “half-thickness” for lead, that is, the thickness of lead that would absorb half the incident gamma rays. (b) What thickness reduces the radiation by a factor of $10^2$?

34. When gamma rays are incident on matter, the intensity of the gamma rays passing through the material varies with depth $x$ as $I(x) = I_0 e^{-\mu x}$, where $I_0$ is the intensity of the radiation at the surface of the material (at $x = 0$) and $\mu$ is the linear absorption coefficient. (a) Determine
35. Review. A particular radioactive source produces 100 mrad of 2.00-MeV gamma rays per hour at a distance of 1.00 m from the source. (a) How long could a person stand at this distance before accumulating an intolerable dose of 1.00 rem? (b) What If? Assuming the radioactive source is a point source, at what distance would a person receive a dose of 10.0 mrad/h?

36. A person whose mass is 75.0 kg is exposed to a whole-body dose of 0.250 Gy. How many joules of energy are deposited in the person’s body?

37. Review. The danger to the body from a high dose of gamma rays is not due to the amount of energy absorbed; rather, it is due to the ionizing nature of the radiation. As an illustration, calculate the rise in body temperature that results if a “lethal” dose of 1 000 rad is absorbed strictly as internal energy. Take the specific heat of living tissue as 4.186 J/kg · °C.

38. Review. Why is the following situation impossible? A “clever” technician takes his 20-min coffee break and boils some water for his coffee with an x-ray machine. The machine produces 10.0 rad/s, and the temperature of the water in an insulated cup is initially 50.0°C.

39. A small building has become accidentally contaminated with radioactive material. The longest-lived material in the building is strontium-90. (Sr has an atomic mass 89.907 u, and its half-life is 29.1 yr. It is particularly dangerous because it substitutes for calcium in bones.) Assume the building initially contained 5.00 kg of this substance uniformly distributed throughout the building and the safe level is defined as less than 10.0 decays/min (which is small compared with background radiation). How long will the building be unsafe?

40. Technetium-99 is used in certain medical diagnostic procedures. Assume 1.00 × 10⁻³ g of ⁹⁹Tc is injected into a 60.0-kg patient and half of the 0.140-MeV gamma rays are absorbed in the body. Determine the total radiation dose received by the patient.

41. To destroy a cancerous tumor, a dose of gamma radiation with a total energy of 2.12 J is to be delivered in 30.0 days from implanted sealed capsules containing palladium-103. Assume this isotope has a half-life of 17.0 d and emits gamma rays of energy 21.0 keV, which are entirely absorbed within the tumor. (a) Find the initial activity of the set of capsules. (b) Find the total mass of radioactive palladium these “seeds” should contain.

42. Strontium-90 from the testing of nuclear bombs can still be found in the atmosphere. Each decay of ⁹⁰Sr releases 1.10 MeV of energy into the bones of a person who has had strontium replace his or her body’s calcium. Assume a 70.0-kg person receives 1.00 ng of ⁹⁰Sr from contaminated milk. Take the half-life of ⁹⁰Sr to be 29.1 yr. Calculate the absorbed dose rate (in joules per kilogram) in one year.

**Section 45.6 Uses of Radiation**

43. When gamma rays are incident on matter, the intensity of the gamma rays passing through the material varies with depth x as

\[ I(x) = I_0 e^{-\mu x}, \]

where \( I_0 \) is the intensity of the radiation at the surface of the material (at \( x = 0 \)) and \( \mu \) is the linear absorption coefficient. For low-energy gamma rays in steel, take the absorption coefficient to be 0.720 mm⁻¹. (a) Determine the “half-thickness” for steel, that is, the thickness of steel that would absorb half the incident gamma rays. (b) In a steel mill, the thickness of sheet steel passing into a roller is measured by monitoring the intensity of gamma radiation reaching a detector below the rapidly moving metal from a small source immediately above the metal. If the thickness of the sheet changes from 0.800 mm to 0.700 mm, by what percentage does the gamma-ray intensity change?

44. A method called neutron activation analysis can be used for chemical analysis at the level of isotopes. When a sample is irradiated by neutrons, radioactive atoms are produced continuously and then decay according to their characteristic half-lives. (a) Assume one species of radioactive nuclei is produced at a constant rate \( R \) and its decay is described by the conventional radioactive decay law. Assuming irradiation begins at time \( t = 0 \), show that the number of radioactive atoms accumulated at time \( t \) is

\[ N = \frac{R}{\lambda} (1 - e^{-\lambda t}) \]

(b) What is the maximum number of radioactive atoms that can be produced?

45. You want to find out how many atoms of the isotope ⁶⁵Cu are in a small sample of material. You bombard the sample with neutrons to ensure that on the order of 1% of these copper nuclei absorb a neutron. After activation, you turn off the neutron flux and then use a highly efficient detector to monitor the gamma radiation that comes out of the sample. Assume half of the ⁶⁵Cu nuclei emit a 1.04-MeV gamma ray in their decay. (The other half of the activated nuclei decay directly to the ground state of ⁶⁶Ni.) If after 10 min (two half-lives) you have detected 1.00 × 10⁴ MeV of photon energy at 1.04 MeV, (a) approximately how many ⁶⁵Cu atoms are in the sample? (b) Assume the sample contains natural copper. Refer to the isotopic abundances listed in Table 44.2 and estimate the total mass of copper in the sample.

**Additional Problems**

46. A fusion reaction that has been considered as a source of energy is the absorption of a proton by a boron-11 nucleus to produce three alpha particles:

\[ _1^1\text{H} + _3^7\text{B} \rightarrow 3(\alpha) \]
This reaction is an attractive possibility because boron is easily obtained from the Earth’s crust. A disadvantage is that the protons and boron nuclei must have large kinetic energies for the reaction to take place. This requirement contrasts with the initiation of uranium fission by slow neutrons. (a) How much energy is released in each reaction? (b) Why must the reactant particles have high kinetic energies?

47. Review. A very slow neutron (with speed approximately equal to zero) can initiate the reaction

\[ ^{1}n + ^{10}B \rightarrow ^{3}Li + ^{4}He \]

The alpha particle moves away with speed 9.25 \times 10^6 \text{ m/s}. Calculate the kinetic energy of the lithium nucleus. Use nonrelativistic equations.

48. Review. The first nuclear bomb was a fissioning mass of plutonium-239 that exploded in the Trinity test before dawn on July 16, 1945, at Alamogordo, New Mexico. Enrico Fermi was 14 km away, lying on the ground facing away from the bomb. After the whole sky had flashed with unbelievable brightness, Fermi stood up and began dropping bits of paper to the ground. They first fell at his feet in the calm and silent air. As the shock wave passed, about 40 s after the explosion, the paper then in flight jumped approximately 2.5 m away from ground zero. (a) Equation 17.10 describes the relationship between the pressure amplitude \( \Delta P_{\text{max}} \) of a sinusoidal air compression wave and its displacement amplitude \( s_{\text{max}} \). The compression pulse produced by the bomb explosion was not a sinusoidal wave, but let’s use the same equation to compute an estimate for the pressure amplitude, taking \( \omega \sim 1 \text{ s}^{-1} \) as an estimate for the angular frequency at which the pulse ramps up and down. (b) Find the change in volume \( \Delta V \) of a sphere of radius 14 km when its radius increases by 2.5 m. (c) The energy carried by the blast wave is the work done by one layer of air on the next as the wave crest passes. An extension of the logic used to derive Equation 20.8 shows that this work is given by \( \frac{\Delta P_{\text{max}}}{\Delta V} \). Compute an estimate for this energy. (d) Assume the blast wave carried on the order of one-tenth of the explosion’s energy. Make an order-of-magnitude estimate of the bomb yield. (e) One ton of exploding TNT releases 4.2 GJ of energy. What was the order of magnitude of the energy of the Trinity test in equivalent tons of TNT? Fermi’s immediate knowledge of the bomb yield agreed with that determined days later by analysis of elaborate measurements.

49. On August 6, 1945, the United States dropped on Hiroshima a nuclear bomb that released 5 \times 10^{13} \text{ J} of energy, equivalent to that from 12 000 tons of TNT. The fission of one \(^{235}\text{U} \) nucleus releases an average of 208 MeV. Estimate (a) the number of nuclei fissioned and (b) the mass of this \(^{235}\text{U} \).

50. (a) A student wishes to measure the half-life of a radioactive substance using a small sample. Consecutive clicks of her radiation counter are randomly spaced in time. The counter registers 372 counts during one 5.00-min interval and 337 counts during the next 5.00 min. The average background rate is 15 counts per minute. Find the most probable value for the half-life. (b) Estimate the uncertainty in the half-life determination in part (a). Explain your reasoning.

51. In a Geiger–Mueller tube for detecting radiation (see Problem 68 in Chapter 25), the voltage between the electrodes is typically 1.00 kV and the current pulse discharges a 5.00-pF capacitor. (a) What is the energy amplification of this device for a 0.500-MeV electron? (b) How many electrons participate in the avalanche caused by the single initial electron?

52. Review. Consider a nucleus at rest, which then spontaneously splits into two fragments of masses \( m_1 \) and \( m_2 \). (a) Show that the fraction of the total kinetic energy carried by fragment \( m_1 \) is

\[ \frac{K_1}{K_{\text{tot}}} = \frac{m_2}{m_1 + m_2} \]

and the fraction carried by \( m_2 \) is

\[ \frac{K_2}{K_{\text{tot}}} = \frac{m_1}{m_1 + m_2} \]

assuming relativistic corrections can be ignored. A stationary \(^{235}\text{U} \) nucleus fissions spontaneously into two primary fragments, \(^{55}\text{Br} \) and \(^{180}\text{La} \). (b) Calculate the disintegration energy. The required atomic masses are 86.920 711 u for \(^{55}\text{Br} \), 148.934 370 u for \(^{180}\text{La} \), and 236.045 562 u for \(^{235}\text{U} \). (c) How is the disintegration energy split between the two primary fragments? (d) Calculate the speed of each fragment immediately after the fission.

53. Consider the carbon cycle in Problem 30. (a) Calculate the \( Q \) value for each of the six steps in the carbon cycle listed in Problem 30. (b) In the second and fifth steps of the cycle, the positron that is ejected combines with an electron to form two photons. The energies of these photons must be included in the energy released in the cycle. How much energy is released by these annihilations in each of the two steps? (c) What is the overall energy released in the carbon cycle? (d) Do you think that the energy carried off by the neutrinos is deposited in the stars? Explain.

54. A fission reactor is hit by a missile, and 5.00 \times 10^{10} \text{ Ci} of \(^{90}\text{Sr} \), with half-life 29.1 yr, evaporates into the air. The strontium falls out over an area of 10^4 \text{ km}^2. After what time interval will the activity of the \(^{90}\text{Sr} \) reach the agriculturally "safe" level of 2.00 \mu\text{Ci}/\text{m}^2?

55. The alpha-emitter plutonium-238 (\(^{238}\text{Pu} \), atomic mass 238.049 560 u, half-life 87.7 yr) was used in a nuclear energy source on the Apollo Lunar Surface Experiments Package (Fig. P45.55, page 1444). The energy source, called the Radiosotope Thermoelectric Generator, is the small gray object to the left of the gold-shrouded Central Station in the photograph. Assume the source contains 3.80 kg of \(^{238}\text{Pu} \) and the efficiency
for conversion of radioactive decay energy to energy transferred by electrical transmission is 3.20%. Determine the initial power output of the source.

**Figure P45.55**

65. The half-life of tritium is 12.3 yr. (a) If the TFTR fusion reactor contained 50.0 m³ of tritium at a density equal to 2.00 × 10¹⁴ ions/cm³, how many curies of tritium were in the plasma? (b) State how this value compares with a fission inventory (the estimated supply of fissionable material) of 4.00 × 10¹⁰ Ci.

66. Review. A nuclear power plant operates by using the energy released in nuclear fission to convert 20°C water into 400°C steam. How much water could theoretically be converted to steam by the complete fissioning of 1.00 g of ²³⁵U at 200 MeV/fission?

67. Review. A nuclear power plant operates by using the energy released in nuclear fission to convert liquid water at Tᵣ into steam at Tₛ. How much water could theoretically be converted to steam by the complete fissioning of a mass m of ²³⁵U if the energy released per fission event is E?

68. Consider the two nuclear reactions

\[
\begin{align*}
A + B & \rightarrow C + E \\
C + D & \rightarrow F + G 
\end{align*}
\]

(a) Show that the net disintegration energy for these two reactions (\(Q_{\text{net}} = Q₄ + Q₅\)) is identical to the disintegration energy for the net reaction

\[
A + B + D \rightarrow E + F + G
\]

(b) One chain of reactions in the proton–proton cycle in the Sun’s core is

\[
\begin{align*}
^{1}\text{H} + ^{1}\text{H} & \rightarrow ^{2}\text{H} + ^{0}\text{e} + \nu \\
^{0}\text{e} + ^{2}\text{He} & \rightarrow 2\gamma \\
^{1}\text{H} + ^{2}\text{He} & \rightarrow ^{4}\text{He} + ^{0}\text{e} + \nu \\
^{0}\text{e} + ^{2}\text{He} & \rightarrow 2\gamma 
\end{align*}
\]

Based on part (a), what is \(Q_{\text{net}}\) for this sequence?

69. Natural uranium must be processed to produce uranium enriched in ²³⁵U for weapons and power plants. The processing yields a large quantity of nearly pure ²³⁸U as a by-product, called “depleted uranium.” Because of its high mass density, ²³⁸U is used in armor-piercing artillery shells. (a) Find the edge dimension of a 70.0-kg cube of ²³⁸U (\(\rho = 19.1 \times 10^3\) kg/m³). (b) The isotope ²³⁸U has a long half-life of 4.47 × 10⁹ yr. As soon as one nucleus decays, a relatively rapid series of 14 steps begins that together constitute the net reaction

\[
^{238}\text{U} \rightarrow 8(^{4}\text{He}) + 6(^{0}\text{e}) + ^{206}\text{Pb} + 6\gamma + Q_{\text{net}}
\]

Find the net decay energy. (Refer to Table 44.2.)

(c) Argue that a radioactive sample with decay rate \(R\) and decay energy \(Q\) has power output \(P = QR\).

(d) Consider an artillery shell with a jacket of 70.0 kg of ²³⁸U. Find its power output due to the radioactivity of the uranium and its daughters. Assume the shell is old enough that the daughters have reached steady-state amounts. Express the power in joules per year.

(e) What If? A 17-year-old soldier of mass 70.0 kg works in an arsenal where many such artillery shells are stored. Assume his radiation exposure is limited to 5.00 rem per year. Find the rate in joules per year at which he can absorb energy of radiation. Assume an average RBE factor of 1.10.

70. Suppose the target in a laser fusion reactor is a sphere of solid hydrogen that has a diameter of 1.50 × 10⁻⁴ m and a density of 0.200 g/cm³. Assume half of the nuclei are ¹H and half are ²H. (a) If 1.00% of a 200-kJ laser pulse is delivered to this sphere, what temperature does the sphere reach? (b) If all the hydrogen fuses according to the D–T reaction, how many joules of energy are released?

71. When photons pass through matter, the intensity \(I\) of the beam (measured in watts per square meter) decreases exponentially according to

\[
I = I₀e^{-\mu x}
\]

where \(I\) is the intensity of the beam that just passed through a thickness \(x\) of material and \(I₀\) is the intensity of the incident beam. The constant \(\mu\) is known as the linear absorption coefficient, and its value depends on the absorbing material and the wavelength of the pho-
ton beam. This wavelength (or energy) dependence allows us to filter out unwanted wavelengths from a broad-spectrum x-ray beam. (a) Two x-ray beams of wavelengths $\lambda_1$ and $\lambda_2$ and equal incident intensities pass through the same metal plate. Show that the ratio of the emergent beam intensities is

$$\frac{I_2}{I_1} = e^{-(\mu_2-\mu_1)x}$$

(b) Compute the ratio of intensities emerging from an aluminum plate 1.00 mm thick if the incident beam contains equal intensities of 50 pm and 100 pm x-rays. The values of $\mu$ for aluminum at these two wavelengths are $\mu_1 = 5.40 \text{ cm}^{-1}$ at 50 pm and $\mu_2 = 41.0 \text{ cm}^{-1}$ at 100 pm. (c) Repeat part (b) for an aluminum plate 10.0 mm thick.

63. Assume a deuteron and a triton are at rest when they fuse according to the reaction

$$^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + ^1\text{n}$$

Determine the kinetic energy acquired by the neutron.

64. (a) Calculate the energy (in kilowatt-hours) released if 1.00 kg of $^{235}\text{Pu}$ undergoes complete fission and the energy released per fission event is 200 MeV. (b) Calculate the energy (in electron volts) released in the deuterium–tritium fusion reaction

$$^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + ^1\text{n}$$

(c) Calculate the energy (in kilowatt-hours) released if 1.00 kg of deuterium undergoes fusion according to this reaction. (d) What If? Calculate the energy (in kilowatt-hours) released by the combustion of 1.00 kg of carbon in coal if each $\text{C} + \text{O}_2 \rightarrow \text{CO}_2$ reaction yields 4.20 eV. (e) List advantages and disadvantages of each of these methods of energy generation.

65. Consider a 1.00-kg sample of natural uranium composed primarily of $^{235}\text{U}$, a smaller amount (0.720% by mass) of $^{238}\text{U}$, and a trace (0.005 00%) of $^{234}\text{U}$, which has a half-life of 2.44 × 10^7 yr. (a) Find the activity in curies due to each of the isotopes. (b) What fraction of the total activity is due to each isotope? (c) Explain whether the activity of this sample is dangerous.

66. Approximately 1 of every 3 300 water molecules contains one deuterium atom. (a) If all the deuterium nuclei in 1 L of water are fused in pairs according to the D–D fusion reaction $^2\text{H} + ^2\text{H} \rightarrow ^3\text{He} + n + 3.27 \text{ MeV}$, how much energy in joules is liberated? (b) What If? Burning gasoline produces approximately $3.40 \times 10^7 \text{ J/L}$. State how the energy obtainable from the fusion of the deuterium in 1 L of water compares with the energy liberated from the burning of 1 L of gasoline.

67. Carbon detonations are powerful nuclear reactions that temporarily tear apart the cores inside massive stars late in their lives. These blasts are produced by carbon fusion, which requires a temperature of approximately $6 \times 10^8$ K to overcome the strong Coulomb repulsion between carbon nuclei. (a) Estimate the repulsive energy barrier to fusion, using the temperature required for carbon fusion. (In other words, what is the average kinetic energy of a carbon nucleus at $6 \times 10^8$ K? (b) Calculate the energy (in MeV) released in each of these “carbon-burning” reactions:

$$^{12}\text{C} + ^{12}\text{C} \rightarrow ^{20}\text{Ne} + ^4\text{He}$$
$$^{12}\text{C} + ^{12}\text{C} \rightarrow ^{23}\text{Mg} + \gamma$$

(c) Calculate the energy in kilowatt-hours given off when 2.00 kg of carbon completely fuse according to the first reaction.

68. A sealed capsule containing the radiopharmaceutical phosphorus-32, an $\alpha$ emitter, is implanted into a patient’s tumor. The average kinetic energy of the beta particles is 700 keV. The initial activity is 5.22 MBq. Assume the beta particles are completely absorbed in 100 g of tissue. Determine the absorbed dose during a 10.0-day period.

69. A certain nuclear plant generates internal energy at a rate of 3.065 GW and transfers energy out of the plant by electrical transmission at a rate of 1.000 GW. Of the waste energy, 3.0% is ejected to the atmosphere and the remainder is passed into a river. A state law requires that the river water be warmed by no more than 3.50°C when it is returned to the river. (a) Determine the amount of cooling water necessary (in kilograms per hour and cubic meters per hour) to cool the plant. (b) Assume fission generates $7.80 \times 10^{10}$ J of $^{235}\text{U}$. Determine the rate of fuel burning (in kilograms per hour) of $^{235}\text{U}$.

70. The Sun radiates energy at the rate of $3.85 \times 10^{26}$ W. Suppose the net reaction $^4\text{He} + 2(\text{^0e}) \rightarrow ^2\text{He} + 2\nu + \gamma$ accounts for all the energy released. Calculate the number of protons fused per second.

### Challenge Problems

71. During the manufacture of a steel engine component, radioactive iron ($^{56}\text{Fe}$) with a half-life of 45.1 d is included in the total mass of 0.200 kg. The component is placed in a test engine when the activity due to this isotope is 20.0 $\mu$Ci. After a 1 000-h test period, some of the lubricating oil is removed from the engine and found to contain enough $^{56}\text{Fe}$ to produce 800 disintegrations/min/L of oil. The total volume of oil in the engine is 6.50 L. Calculate the total mass worn from the engine component per hour of operation.

72. (a) At time $t = 0$, a sample of uranium is exposed to a neutron source that causes $N_0$ nuclei to undergo fission. The sample is in a supercritical state, with a reproduction constant $K > 1$. A chain reaction occurs that
proliferates fission throughout the mass of uranium. The chain reaction can be thought of as a succession of generations. The \( N_0 \) fissions produced initially are the zeroth generation of fissions. From this generation, \( N_0 K \) neutrons go off to produce fission of new uranium nuclei. The \( N_0 K \) fissions that occur subsequently are the first generation of fissions, and from this generation \( N_0 K^2 \) neutrons go in search of uranium nuclei in which to cause fission. The subsequent \( N_0 K^2 \) fissions are the second generation of fissions. This process can continue until all the uranium nuclei have fissioned. Show that the cumulative total of fissions \( N \) that have occurred up to and including the \( n \)th generation after the zeroth generation is given by

\[
N = N_0 \left( \frac{K^{n+1} - 1}{K - 1} \right)
\]

(b) Consider a hypothetical uranium weapon made from 5.50 kg of isotopically pure \(^{235}\text{U}\). The chain reaction has a reproduction constant of 1.10 and starts with a zeroth generation of \(1.00 \times 10^{20}\) fissions. The average time interval between one fission generation and the next is 10.0 ns. How long after the zeroth generation does it take the uranium in this weapon to fission completely? (c) Assume the bulk modulus of uranium is 150 GPa. Find the speed of sound in uranium. You may ignore the density difference between \(^{235}\text{U}\) and natural uranium. (d) Find the time interval required for a compressional wave to cross the radius of a 5.50-kg sphere of uranium. This time interval indicates how quickly the motion of explosion begins. (e) Fission must occur in a time interval that is short compared with that in part (d); otherwise, most of the uranium will disperse in small chunks without having fissioned. Can the weapon considered in part (b) release the explosive energy of all its uranium? If so, how much energy does it release in equivalent tons of TNT? Assume one ton of TNT releases 4.20 GJ and each uranium fission releases 200 MeV of energy.

73. Assume a photomultiplier tube for detecting radiation has seven dynodes with potentials of 100, 200, 300, . . . , 700 V as shown in Figure P45.73. The average energy required to free an electron from the dynode surface is 10.0 eV. Assume only one electron is incident and the tube functions with 100% efficiency. (a) How many electrons are freed at the first dynode at 100 V? (b) How many electrons are collected at the last dynode? (c) What is the energy available to the counter for all the electrons arriving at the last dynode?
The word atom comes from the Greek atomos, which means “indivisible.” The early Greeks believed that atoms were the indivisible constituents of matter; that is, they regarded them as elementary particles. After 1932, physicists viewed all matter as consisting of three constituent particles: electrons, protons, and neutrons. Beginning in the 1940s, many “new” particles were discovered in experiments involving high-energy collisions between known particles. The new particles are characteristically very unstable and have very short half-lives, ranging between $10^{-6}$ s and $10^{-23}$ s. So far, more than 300 of these particles have been catalogued.

Until the 1960s, physicists were bewildered by the great number and variety of subatomic particles that were being discovered. They wondered whether the particles had no systematic relationship connecting them or whether a pattern was emerging that would provide a better understanding of the elaborate structure in the subatomic world. For example, that the neutron has a magnetic moment despite having zero electric charge (Section 44.8) suggests an underlying structure to the neutron. The periodic table explains how more than 100 elements can be formed from three types of particles (electrons, protons, and...
neutrons), which suggests there is, perhaps, a means of forming more than 300 subatomic particles from a small number of basic building blocks.

Recall Figure 1.2, which illustrated the various levels of structure in matter. We studied the atomic structure of matter in Chapter 42. In Chapter 44, we investigated the substructure of the atom by describing the structure of the nucleus. As mentioned in Section 1.2, the protons and neutrons in the nucleus, and a host of other exotic particles, are now known to be composed of six different varieties of particles called quarks. In this concluding chapter, we examine the current theory of elementary particles, in which all matter is constructed from only two families of particles, quarks and leptons. We also discuss how clarifications of such models might help scientists understand the birth and evolution of the Universe.

46.1 The Fundamental Forces in Nature

As noted in Section 5.1, all natural phenomena can be described by four fundamental forces acting between particles. In order of decreasing strength, they are the nuclear force, the electromagnetic force, the weak force, and the gravitational force.

The nuclear force discussed in Chapter 44 is an attractive force between nucleons. It has a very short range and is negligible for separation distances between nucleons greater than approximately $10^{-15}$ m (about the size of the nucleus). The electromagnetic force, which binds atoms and molecules together to form ordinary matter, has a strength of approximately $10^{-2}$ times that of the nuclear force. This long-range force decreases in magnitude as the inverse square of the separation between interacting particles. The weak force is a short-range force that tends to produce instability in certain nuclei. It is responsible for decay processes, and its strength is only about $10^{-5}$ times that of the nuclear force. Finally, the gravitational force is a long-range force that has a strength of only about $10^{-39}$ times that of the nuclear force. Although this familiar interaction is the force that holds the planets, stars, and galaxies together, its effect on elementary particles is negligible.

In Section 13.3, we discussed the difficulty early scientists had with the notion of the gravitational force acting at a distance, with no physical contact between the interacting objects. To resolve this difficulty, the concept of the gravitational field was introduced. Similarly, in Chapter 23, we introduced the electric field to describe the electric force acting between charged objects, and we followed that with a discussion of the magnetic field in Chapter 29. For each of these types of fields, we developed a particle in a field analysis model. In modern physics, the nature of the interaction between particles is carried a step further. These interactions are described in terms of the exchange of entities called field particles or exchange particles. Field particles are also called gauge bosons. The interacting particles continuously emit and absorb field particles. The emission of a field particle by one particle and its absorption by another manifests as a force between the two interacting particles. In the case of the electromagnetic interaction, for instance, the field particles are photons. In the language of modern physics, the electromagnetic force is said to be mediated by photons, and photons are the field particles of the electromagnetic field. Likewise, the nuclear force is mediated by field particles called gluons. The weak force is mediated by field particles called $W$ bosons and $Z$ bosons, and the gravitational force is proposed to be mediated by field particles called gravitons. These interactions, their ranges, and their relative strengths are summarized in Table 46.1.

---

1The word bosons suggests that the field particles have integral spin as discussed in Section 43.8. The word gauge comes from gauge theory, which is a sophisticated mathematical analysis that is beyond the scope of this book.

46.2  Positrons and Other Antiparticles

In the 1920s, Paul Dirac developed a relativistic quantum-mechanical description of the electron that successfully explained the origin of the electron’s spin and its magnetic moment. His theory had one major problem, however: its relativistic wave equation required solutions corresponding to negative energy states, and if negative energy states existed, an electron in a state of positive energy would be expected to make a rapid transition to one of these states, emitting a photon in the process.

Dirac circumvented this difficulty by postulating that all negative energy states are filled. The electrons occupying these negative energy states are collectively called the Dirac sea. Electrons in the Dirac sea (the blue area in Fig. 46.1) are not directly observable because the Pauli exclusion principle does not allow them to react to external forces; there are no available states to which an electron can make a transition in response to an external force. Therefore, an electron in such a state acts as an isolated system unless an interaction with the environment is strong enough to excite the electron to a positive energy state. Such an excitation causes one of the negative energy states to be vacant as in Figure 46.1, leaving a hole in the sea of filled states. This process is described by the nonisolated system model: as energy enters the system by some transfer mechanism, the system energy increases and the electron is excited to a higher energy level. The hole can react to external forces and is observable. The hole reacts in a way similar to that of the electron except that it has a positive charge: it is the antiparticle to the electron.

This theory strongly suggested that an antiparticle exists for every particle, not only for fermions such as electrons but also for bosons. It has subsequently been verified that practically every known elementary particle has a distinct antiparticle. Among the exceptions are the photon and the neutral pion (π0; see Section 46.3). Following the construction of high-energy accelerators in the 1950s, many other antiparticles were revealed. They included the antiproton, discovered by Emilio Segré (1905–1989) and Owen Chamberlain (1920–2006) in 1955, and the antineutron, discovered shortly thereafter. The antiparticle for a charged particle has the same mass as the particle but opposite charge. For example, the electron’s antiparticle (the positron mentioned in Section 44.4) has a rest energy of 0.511 MeV and a positive charge of +1.60 × 10^{-19} C.

Carl Anderson (1905–1991) observed the positron experimentally in 1932 and was awarded a Nobel Prize in Physics in 1936 for this achievement. Anderson discovered the positron while examining tracks created in a cloud chamber by electron-like particles of positive charge. (These early experiments used cosmic rays—mostly energetic protons passing through interstellar space—to initiate high-energy reactions on the order of several GeV.) To discriminate between positive and negative charges, Anderson placed the cloud chamber in a magnetic field.

\[ E = m_e c^2 \]

An electron can make a transition out of the Dirac sea only if it is provided with energy equal to or larger than \(2m_e c^2\).

\[ E = -m_e c^2 \]

An upward transition of an electron leaves a vacancy in the Dirac sea, which can behave as a particle identical to the electron except for its positive charge.

\[ E = 0 \]

Paul Adrien Maurice Dirac
British Physicist (1902–1984)

Dirac was instrumental in the understanding of antimatter and the unification of quantum mechanics and relativity. He made many contributions to the development of quantum physics and cosmology. In 1933, Dirac won a Nobel Prize in Physics.

causing moving charges to follow curved paths. He noted that some of the electron-like tracks deflected in a direction corresponding to a positively charged particle.

Since Anderson’s discovery, positrons have been observed in a number of experiments. A common source of positrons is **pair production**. In this process, a gamma-ray photon with sufficiently high energy interacts with a nucleus and an electron–positron pair is created from the photon. (The presence of the nucleus allows the principle of conservation of momentum to be satisfied.) Because the total rest energy of the electron–positron pair is $2m_e^2 = 1.02 \text{ MeV}$ (where $m_e$ is the mass of the electron), the photon must have at least this much energy to create an electron–positron pair. The energy of a photon is converted to rest energy of the electron and positron in accordance with Einstein’s relationship $E_R = mc^2$. If the gamma-ray photon has energy in excess of the rest energy of the electron–positron pair, the excess appears as kinetic energy of the two particles. Figure 46.2 shows early observations of tracks of electron–positron pairs in a bubble chamber created by 300-MeV gamma rays striking a lead sheet.

**Quick Quiz 46.1** Given the identification of the particles in Figure 46.2b, is the direction of the external magnetic field in Figure 46.2a (a) into the page, (b) out of the page, or (c) impossible to determine?

The reverse process can also occur. Under the proper conditions, an electron and a positron can annihilate each other to produce two gamma-ray photons that have a combined energy of at least 1.02 MeV:

$$e^- + e^+ \rightarrow 2\gamma$$

Because the initial momentum of the electron–positron system is approximately zero, the two gamma rays travel in opposite directions after the annihilation, satisfying the principle of conservation of momentum for the isolated system.

Electron–positron annihilation is used in the medical diagnostic technique called **positron-emission tomography** (PET). The patient is injected with a glucose solution containing a radioactive substance that decays by positron emission, and the material is carried throughout the body by the blood. A positron emitted during a decay event in one of the radioactive nuclei in the glucose solution annihilates with an electron in the surrounding tissue, resulting in two gamma-ray photons emitted in opposite directions. A gamma detector surrounding the patient pinpoints the source of the photons and, with the assistance of a computer, displays an image of the sites at which the glucose accumulates. (Glucose metabolizes rapidly in cancerous tumors and accumulates at those sites, providing a strong signal for a PET detector system.) The images from a PET scan can indicate a wide variety of disorders in the brain, including Alzheimer’s disease (Fig. 46.3). In addition, because glucose metabolizes more rapidly in active areas...
of the brain, a PET scan can indicate areas of the brain involved in the activities in which the patient is engaging at the time of the scan, such as language use, music, and vision.

### 46.3 Mesons and the Beginning of Particle Physics

Physicists in the mid-1930s had a fairly simple view of the structure of matter. The building blocks were the proton, the electron, and the neutron. Three other particles were either known or postulated at the time: the photon, the neutrino, and the positron. Together these six particles were considered the fundamental constituents of matter. With this simple picture, however, no one was able to answer the following important question: the protons in any nucleus should strongly repel one another due to their charges of the same sign, so what is the nature of the force that holds the nucleus together? Scientists recognized that this mysterious force must be much stronger than anything encountered in nature up to that time. This force is the nuclear force discussed in Section 44.1 and examined in historical perspective in the following paragraphs.

The first theory to explain the nature of the nuclear force was proposed in 1935 by Japanese physicist Hideki Yukawa, an effort that earned him a Nobel Prize in Physics in 1949. To understand Yukawa’s theory, recall the introduction of field particles in Section 46.1, which stated that each fundamental force is mediated by a field particle exchanged between the interacting particles. Yukawa used this idea to explain the nuclear force, proposing the existence of a new particle whose exchange between nucleons in the nucleus causes the nuclear force. He established that the range of the force is inversely proportional to the mass of this particle and predicted the mass to be approximately 200 times the mass of the electron. (Yukawa’s predicted particle is not the gluon mentioned in Section 46.1, which is massless and is today considered to be the field particle for the nuclear force.) Because the new particle would have a mass between that of the electron and that of the proton, it was called a meson (from the Greek meso, “middle”).

In efforts to substantiate Yukawa’s predictions, physicists began experimental searches for the meson by studying cosmic rays entering the Earth’s atmosphere. In 1937, Carl Anderson and his collaborators discovered a particle of mass 106 MeV/c\(^2\), approximately 207 times the mass of the electron. This particle was thought to be Yukawa’s meson. Subsequent experiments, however, showed that the particle interacted very weakly with matter and hence could not be the field particle for the nuclear force. That puzzling situation inspired several theoreticians to propose two mesons having slightly different masses equal to approximately 200 times that of the electron, one having been discovered by Anderson and the other, still undiscovered, predicted by Yukawa. This idea was confirmed in 1947 with the discovery of the \(\pi\) meson (\(\pi\)), or simply pion. The particle discovered by Anderson in 1937, the one initially thought to be Yukawa’s meson, is not really a

---

**Figure 46.3** PET scans of the brain of a healthy older person (left) and that of a patient suffering from Alzheimer’s disease (right). Lighter regions contain higher concentrations of radioactive glucose, indicating higher metabolism rates and therefore increased brain activity.
meson. (We shall discuss the characteristics of mesons in Section 46.4.) Instead, it takes part in the weak and electromagnetic interactions only and is now called the muon ($\mu$).

The pion comes in three varieties, corresponding to three charge states: $\pi^+$, $\pi^-$, and $\pi^0$. The $\pi^+$ and $\pi^-$ particles ($\pi^0$ is the antiparticle of $\pi^+$) each have a mass of 139.6 MeV/c$^2$, and the $\pi^0$ mass is 135.0 MeV/c$^2$. Two muons exist: $\mu^-$ and its antiparticle $\mu^+$.

Pions and muons are very unstable particles. For example, the $\pi^-$, which has a mean lifetime of $2.6 \times 10^{-8}$ s, decays to a muon and an antineutrino. The muon, which has a mean lifetime of 2.2 $\mu$s, then decays to an electron, a neutrino, and an antineutrino:

\[
\pi^- \rightarrow \mu^- + \bar{\nu} \\
\mu^- \rightarrow e^- + \nu + \bar{\nu}
\] (46.1)

For chargeless particles (as well as some charged particles, such as the proton), a bar over the symbol indicates an antiparticle, as for the neutrino in beta decay (see Section 44.5). Other antiparticles, such as $e^+$ and $\mu^+$, use a different notation.

The interaction between two particles can be represented in a simple diagram called a Feynman diagram, developed by American physicist Richard P. Feynman. Figure 46.4 is such a diagram for the electromagnetic interaction between two electrons. A Feynman diagram is a qualitative graph of time on the vertical axis versus space on the horizontal axis. It is qualitative in the sense that the actual values of time and space are not important, but the overall appearance of the graph provides a pictorial representation of the process.

In the simple case of the electron–electron interaction in Figure 46.4, a photon (the field particle) mediates the electromagnetic force between the electrons. Notice that the entire interaction is represented in the diagram as occurring at a single point in time. Therefore, the paths of the electrons appear to undergo a discontinuous change in direction at the moment of interaction. The electron paths shown in Figure 46.4 are different from the actual paths, which would be curved due to the continuous exchange of large numbers of field particles.

In the electron–electron interaction, the photon, which transfers energy and momentum from one electron to the other, is called a virtual photon because it vanishes during the interaction without having been detected. In Chapter 40, we discussed that a photon has energy $E = hf$, where $f$ is its frequency. Consequently, for a system of two electrons initially at rest, the system has energy $2m_e c^2$ before a virtual photon is released and energy $2m_e c^2 + hf$ after the virtual photon is released (plus any kinetic energy of the electron resulting from the emission of the photon). Is that a violation of the law of conservation of energy for an isolated system? No; this process does not violate the law of conservation of energy because the virtual photon is created and destroyed in the interaction process.

3The antineutrino is another zero-charge particle for which the identification of the antiparticle is more difficult than that for a charged particle. Although the details are beyond the scope of this book, the neutrino and antineutrino can be differentiated by means of the relationship between the linear momentum and the spin angular momentum of the particles.
photon has a very short lifetime $\Delta t$ that makes the uncertainty in the energy $\Delta E \approx \hbar/2 \Delta t$ of the system greater than the photon energy. Therefore, within the constraints of the uncertainty principle, the energy of the system is conserved.

Now consider a pion exchange between a proton and a neutron according to Yukawa’s model (Fig. 46.5a). The energy $\Delta E_R$ needed to create a pion of mass $m_p$ is given by Einstein’s equation $\Delta E_R = m_p c^2$. As with the photon in Figure 46.4, the very existence of the pion would appear to violate the law of conservation of energy if the particle existed for a time interval greater than $\Delta t = \hbar/2 \Delta E_R$ (from the uncertainty principle), where $\Delta t$ is the time interval required for the pion to transfer from one nucleon to the other. Therefore,

$$\Delta t = \frac{\hbar}{2 \Delta E_R} = \frac{\hbar}{2 m_p c^2}$$

and the rest energy of the pion is

$$m_p c^2 = \frac{\hbar}{2 \Delta t} \quad (46.2)$$

Because the pion cannot travel faster than the speed of light, the maximum distance $d$ it can travel in a time interval $\Delta t$ is $c \Delta t$. Therefore, using Equation 46.2 and $d = c \Delta t$, we find

$$m_p c^2 = \frac{\hbar c}{2 d} \quad (46.3)$$

From Table 46.1, we know that the range of the nuclear force is on the order of $10^{-15}$ fm. Using this value for $d$ in Equation 46.3, we estimate the rest energy of the pion to be

$$m_p c^2 \approx \frac{(1.055 \times 10^{-34} \text{ J} \cdot \text{s})(3.00 \times 10^8 \text{ m/s})}{2 (1 \times 10^{-15} \text{ m})}$$

$$= 1.6 \times 10^{-11} \text{ J} \approx 100 \text{ MeV}$$

which corresponds to a mass of 100 MeV/c$^2$ (approximately 200 times the mass of the electron). This value is in reasonable agreement with the observed pion mass.

The concept just described is quite revolutionary. In effect, it says that a system of two nucleons can change into two nucleons plus a pion as long as it returns to its original state in a very short time interval. (Remember that this description is the older historical model, which assumes the pion is the field particle for the nuclear force; the gluon is the actual field particle in current models.) Physicists often say that a nucleon undergoes fluctuations as it emits and absorbs field particles. These fluctuations are a consequence of a combination of quantum mechanics (through the uncertainty principle) and special relativity (through Einstein’s energy–mass relationship $E_R = mc^2$).
In this section, we discussed the field particles that were originally proposed to mediate the nuclear force (pions) and those that mediate the electromagnetic force (photons). The graviton, the field particle for the gravitational force, has yet to be observed. In 1983, W⁻ and Z⁰ particles, which mediate the weak force, were discovered by Italian physicist Carlo Rubbia (b. 1934) and his associates, using a proton–antiproton collider. Rubbia and Simon van der Meer (1925–2011), both at CERN,¹ shared the 1984 Nobel Prize in Physics for the discovery of the W⁻ and Z⁰ particles and the development of the proton–antiproton collider. Figure 46.5b shows a Feynman diagram for a weak interaction mediated by a Z⁰ boson.

### Classification of Particles

All particles other than field particles can be classified into two broad categories, hadrons and leptons. The criterion for separating these particles into categories is whether or not they interact via the strong force. The nuclear force between nucleons in a nucleus is a particular manifestation of the strong force, but we will use the term strong force to refer to any interaction between particles made up of quarks. (For more detail on quarks and the strong force, see Section 46.8.) Table 46.2 provides a summary of the properties of hadrons and leptons.

¹CERN was originally the Conseil Européen pour la Recherche Nucléaire; the name has been altered to the European Organization for Nuclear Research, and the laboratory operated by CERN is called the European Laboratory for Particle Physics. The CERN acronym has been retained and is commonly used to refer to both the organization and the laboratory.
Hadrons

Particles that interact through the strong force (as well as through the other fundamental forces) are called hadrons. The two classes of hadrons, mesons and baryons, are distinguished by their masses and spins.

Mesons all have zero or integer spin (0 or 1). As indicated in Section 46.3, the name comes from the expectation that Yukawa’s proposed meson mass would lie between the masses of the electron and the proton. Several meson masses do lie in this range, although mesons having masses greater than that of the proton have been found to exist.

All mesons decay finally into electrons, positrons, neutrinos, and photons. The pions are the lightest known mesons and have masses of approximately $1.4 \times 10^3$ MeV/c$^2$, and all three pions—$\pi^+$, $\pi^-$, and $\pi^0$—have a spin of 0. (This spin-0 characteristic indicates that the particle discovered by Anderson in 1937, the muon, is not a meson. The muon has spin $\frac{1}{2}$ and belongs in the lepton classification, described below.)

Baryons, the second class of hadrons, have masses equal to or greater than the proton mass (the name baryon means “heavy” in Greek), and their spin is always a half-integer value ($\frac{1}{2}$, $\frac{3}{2}$, . . .). Protons and neutrons are baryons, as are many other particles. With the exception of the proton, all baryons decay in such a way that the end products include a proton. For example, the baryon called the $\Xi^0$ hyperon (Greek letter xi) decays to the $\Lambda^0$ baryon (Greek letter lambda) in approximately $10^{-10}$ s. The $\Lambda^0$ then decays to a proton and a $\pi^-$ in approximately $3 \times 10^{-10}$ s.

Today it is believed that hadrons are not elementary particles but instead are composed of more elementary units called quarks, per Section 46.8.

Leptons

Leptons (from the Greek leptos, meaning “small” or “light”) are particles that do not interact by means of the strong force. All leptons have spin $\frac{1}{2}$. Unlike hadrons, which have size and structure, leptons appear to be truly elementary, meaning that they have no structure and are point-like.

Quite unlike the case with hadrons, the number of known leptons is small. Currently, scientists believe that only six leptons exist: the electron, the muon, the tau, and a neutrino associated with each: $e^-$, $\mu^-$, $\tau^-$, $\nu_e$, $\nu_\mu$, and $\nu_\tau$. The tau lepton, discovered in 1975, has a mass about twice that of the proton. Direct experimental evidence for the neutrino associated with the tau was announced by the Fermi National Accelerator Laboratory (Fermilab) in July 2000. Each of the six leptons has an antiparticle.

Current studies indicate that neutrinos have a small but nonzero mass. If they do have mass, they cannot travel at the speed of light. In addition, because so many neutrinos exist, their combined mass may be sufficient to cause all the matter in the Universe to eventually collapse into a single point, which might then explode and create a completely new Universe! We shall discuss this possibility in more detail in Section 46.11.

46.5 Conservation Laws

The laws of conservation of energy, linear momentum, angular momentum, and electric charge for an isolated system provide us with a set of rules that all processes must follow. In Chapter 44, we learned that conservation laws are important for understanding why certain radioactive decays and nuclear reactions occur and others do not. In the study of elementary particles, a number of additional conservation laws are important. Although the two described here have no theoretical foundation, they are supported by abundant empirical evidence.
Baryon Number

Experimental results show that whenever a baryon is created in a decay or nuclear reaction, an antibaryon is also created. This scheme can be quantified by assigning every particle a quantum number, the baryon number, as follows: \( B = +1 \) for all baryons, \( B = -1 \) for all antibaryons, and \( B = 0 \) for all other particles. (See Table 46.2.) The law of conservation of baryon number states that whenever a nuclear reaction or decay occurs, the sum of the baryon numbers before the process must equal the sum of the baryon numbers after the process.

If baryon number is conserved, the proton must be absolutely stable. For example, a decay of the proton to a positron and a neutral pion would satisfy conservation of energy, momentum, and electric charge. Such a decay has never been observed, however. The law of conservation of baryon number would be consistent with the absence of this decay because the proposed decay would involve the loss of a baryon. Based on experimental observations as pointed out in Example 46.2, all we can say at present is that protons have a half-life of at least \( 10^{33} \) years (the estimated age of the Universe is only \( 10^{10} \) years). Some recent theories, however, predict that the proton is unstable. According to this theory, baryon number is not absolutely conserved.

Quick Quiz 46.2 Consider the decays (i) \( n \rightarrow \pi^+ + \pi^- + \mu^+ + \mu^- \) and (ii) \( n \rightarrow p + \pi^- \). From the following choices, which conservation laws are violated by each decay? (a) energy (b) electric charge (c) baryon number (d) angular momentum (e) no conservation laws

Example 46.1 Checking Baryon Numbers

Use the law of conservation of baryon number to determine whether each of the following reactions can occur:

(A) \( p + n \rightarrow p + p + n + \bar{\beta} \)

Solution

Conceptualize The mass on the right is larger than the mass on the left. Therefore, one might be tempted to claim that the reaction violates energy conservation. The reaction can indeed occur, however, if the initial particles have sufficient kinetic energy to allow for the increase in rest energy of the system.

Categorize We use a conservation law developed in this section, so we categorize this example as a substitution problem.

Evaluate the total baryon number for the left side of the reaction:

\[ 1 + 1 = 2 \]

Evaluate the total baryon number for the right side of the reaction:

\[ 1 + 1 + 1 + (-1) = 2 \]

Therefore, baryon number is conserved and the reaction can occur.

(B) \( p + n \rightarrow p + p + \bar{\beta} \)

Solution

Evaluate the total baryon number for the left side of the reaction:

\[ 1 + 1 = 2 \]

Evaluate the total baryon number for the right side of the reaction:

\[ 1 + 1 + (-1) = 1 \]

Because baryon number is not conserved, the reaction cannot occur.
Example 46.2  Detecting Proton Decay

Measurements taken at two neutrino detection facilities, the Irvine–Michigan–Brookhaven detector (Fig. 46.6) and the Super Kamiokande in Japan, indicate that the half-life of protons is at least $10^{33}$ yr.

(A) Estimate how long we would have to watch, on average, to see a proton in a glass of water decay.

**Solution**

**Conceptualize** Imagine the number of protons in a glass of water. Although this number is huge, the probability of a single proton undergoing decay is small, so we would expect to wait for a long time interval before observing a decay.

**Categorize** Because a half-life is provided in the problem, we categorize this problem as one in which we can apply our statistical analysis techniques from Section 44.4.

**Analyze** Let’s estimate that a drinking glass contains a number of moles $n$ of water, with a mass of $m = 250$ g and a molar mass $M = 18$ g/mol.

Find the number of molecules of water in the glass:

$$N_{\text{molecules}} = nN_A = \frac{m}{M}N_A$$

Each water molecule contains one proton in each of its two hydrogen atoms plus eight protons in its oxygen atom, for a total of ten protons. Therefore, there are $N = 10N_{\text{molecules}}$ protons in the glass of water.

Find the activity of the protons from Equation 44.7:

$$R = \lambda N = \frac{\ln 2}{T_{1/2}} \left( \frac{10}{M}N_A \right) = \frac{\ln 2}{10^{33} \text{ yr}} \left( \frac{250 \text{ g}}{18 \text{ g/mol}} \right) \left( 6.02 	imes 10^{23} \text{ mol}^{-1} \right)$$

$$= 5.8 \times 10^{-8} \text{ yr}^{-1}$$

**Finalize** The decay constant represents the probability that one proton decays in one year. The probability that any proton in our glass of water decays in the one-year interval is given by Equation (1). Therefore, we must watch our glass of water for $1/R < 17$ million years! That indeed is a long time interval, as expected.

(B) The Super Kamiokande neutrino facility contains 50 000 metric tons of water. Estimate the average time interval between detected proton decays in this much water if the half-life of a proton is $10^{33}$ yr.

**Solution**

Substitute numerical values:

$$R_{\text{Kamiokande}} = \frac{N_{\text{Kamiokande}}}{N_{\text{glass}}}R_{\text{glass}}$$

The number of protons is proportional to the mass of the sample, so express the decay rate in terms of mass:

$$R_{\text{Kamiokande}} = \frac{m_{\text{Kamiokande}}}{m_{\text{glass}}}R_{\text{glass}}$$

Substitute numerical values:

$$R_{\text{Kamiokande}} = \frac{50 \times 10^4 \text{ metric tons}}{0.250 \text{ kg}} \left( \frac{1000 \text{ kg}}{1 \text{ metric ton}} \right) \left( 5.8 \times 10^{-8} \text{ yr}^{-1} \right) \approx 12 \text{ yr}^{-1}$$

**Finalize** The average time interval between decays is about one-twelfth of a year, or approximately one month. That is much shorter than the time interval in part (A) due to the tremendous amount of water in the detector facility. Despite this rosy prediction of one proton decay per month, a proton decay has never been observed. This suggests that the half-life of the proton may be larger than $10^{33}$ years or that proton decay simply does not occur.
Lepton Number

There are three conservation laws involving lepton numbers, one for each variety of lepton. The law of conservation of electron lepton number states that whenever a nuclear reaction or decay occurs, the sum of the electron lepton numbers before the process must equal the sum of the electron lepton numbers after the process.

The electron and the electron neutrino are assigned an electron lepton number $L_e = 1$, and the antileptons $e^-$ and $\bar{\nu}_e$ are assigned an electron lepton number $L_e = 2$. All other particles have $L_e = 0$. For example, consider the decay of the neutron:

$$n \rightarrow p + e^- + \bar{\nu}_e$$

Before the decay, the electron lepton number is $L_e = 0$; after the decay, it is $0 + 1 + (-1) = 0$. Therefore, electron lepton number is conserved. (Baryon number must also be conserved, of course, and it is: before the decay, $B = +1$, and after the decay, $B = +1 + 0 + 0 = +1$.)

Similarly, when a decay involves muons, the muon lepton number $L_\mu$ is conserved. The $\mu^-$ and the $\nu_\mu$ are assigned a muon lepton number $L_\mu = 1$, and the antimuons $\mu^+$ and $\bar{\nu}_\mu$ are assigned a muon lepton number $L_\mu = -1$. All other particles have $L_\mu = 0$.

Finally, tau lepton number $L_\tau$ is conserved with similar assignments made for the tau lepton, its neutrino, and their two antiparticles.

Quick Quiz 46.3 Consider the following decay: $\pi^0 \rightarrow \mu^- + e^+ + \nu_\mu$. What conservation laws are violated by this decay? (a) energy (b) angular momentum (c) electric charge (d) baryon number (e) electron lepton number (f) muon lepton number (g) tau lepton number (h) no conservation laws

Quick Quiz 46.4 Suppose a claim is made that the decay of the neutron is given by $n \rightarrow p + e^-$. What conservation laws are violated by this decay? (a) energy (b) angular momentum (c) electric charge (d) baryon number (e) electron lepton number (f) muon lepton number (g) tau lepton number (h) no conservation laws

Example 46.3 Checking Lepton Numbers

Use the law of conservation of lepton numbers to determine whether each of the following decay schemes (A) and (B) can occur:

(A) $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$

Solution

Conceptualize Because this decay involves a muon and an electron, $L_\mu$ and $L_e$ must each be conserved separately if the decay is to occur.

Categorize We use a conservation law developed in this section, so we categorize this example as a substitution problem.

Evaluate the lepton numbers before the decay:

$\mu^- = +1 \quad L_e = 0$

Evaluate the total lepton numbers after the decay:

$L_\mu = 0 + 0 + 1 = +1 \quad L_e = +1 + (-1) + 0 = 0$

Therefore, both numbers are conserved and on this basis the decay is possible.

(B) $\pi^- \rightarrow \mu^- + \nu_\mu + e^- + \bar{\nu}_e$
Strange particles and Strangeness

Many particles discovered in the 1950s were produced by the interaction of pions with protons and neutrons in the atmosphere. A group of these—the kaon (K), lambda (Λ), and sigma (Σ) particles—exhibited unusual properties both as they were created and as they decayed; hence, they were called strange particles.

One unusual property of strange particles is that they are always produced in pairs. For example, when a pion collides with a proton, a highly probable result is the production of two neutral strange particles (Fig. 46.7):

\[ \pi^- + p \rightarrow K^0 + \Lambda^0 \]

The reaction \( \pi^- + p \rightarrow K^0 + n \), where only one final particle is strange, never occurs, however, even though no previously known conservation laws would be violated and even though the energy of the pion is sufficient to initiate the reaction.

The second peculiar feature of strange particles is that although they are produced in reactions involving the strong interaction at a high rate, they do not decay into particles that interact via the strong force at a high rate. Instead, they decay very slowly, which is characteristic of the weak interaction. Their half-lives are in...
the range $10^{-10}$ s to $10^{-8}$ s, whereas most other particles that interact via the strong force have much shorter lifetimes on the order of $10^{-23}$ s.

To explain these unusual properties of strange particles, a new quantum number $S$, called \textbf{strangeness}, was introduced, together with a conservation law. The strangeness numbers for some particles are given in Table 46.2. The production of strange particles in pairs is handled mathematically by assigning $S = +1$ to one of the particles, $S = -1$ to the other, and $S = 0$ to all nonstrange particles. The \textbf{law of conservation of strangeness} states that

\textbf{Conservation of strangeness} \hspace{1cm} \textbf{in a nuclear reaction or decay that occurs via the strong force, strangeness is conserved; that is, the sum of the strangeness numbers before the process must equal the sum of the strangeness numbers after the process. In processes that occur via the weak interaction, strangeness may not be conserved.}

The low decay rate of strange particles can be explained by assuming the strong and electromagnetic interactions obey the law of conservation of strangeness but the weak interaction does not. Because the decay of a strange particle involves the loss of one strange particle, it violates strangeness conservation and hence proceeds slowly via the weak interaction.

\textbf{Example 46.4} \hspace{1cm} \textbf{Is Strangeness Conserved?}

\textbf{(A)} Use the law of strangeness conservation to determine whether the reaction $\pi^0 + n \rightarrow K^+ + \Sigma^-$ occurs.

\textbf{Solution}

\textbf{Conceptualize} We recognize that there are strange particles appearing in this reaction, so we see that we will need to investigate conservation of strangeness.

\textbf{Categorize} We use a conservation law developed in this section, so we categorize this example as a substitution problem.

Evaluate the strangeness for the left side of the reaction: $S = 0 + 0 = 0$

Evaluate the strangeness for the right side of the reaction: $S = +1 - 1 = 0$

Therefore, strangeness is conserved and the reaction is allowed.

\textbf{(B)} Show that the reaction $\pi^- + p \rightarrow \pi^- + \Sigma^+$ does not conserve strangeness.

\textbf{Solution}

Evaluate the strangeness for the left side of the reaction: $S = 0 + 0 = 0$

Evaluate the strangeness for the right side of the reaction: $S = 0 + (-1) = -1$

Therefore, strangeness is not conserved.

\section*{46.7 Finding Patterns in the Particles}

One tool scientists use is the detection of patterns in data, patterns that contribute to our understanding of nature. For example, Table 21.2 shows a pattern of molar specific heats of gases that allows us to understand the differences among monatomic, diatomic, and polyatomic gases. Figure 42.20 shows a pattern of peaks in the ionization energy of atoms that relate to the quantized energy levels in the
Finding Patterns in the Particles

Figure 44.7 shows a pattern of peaks in the binding energy that suggest a shell structure within the nucleus. One of the best examples of this tool’s use is the development of the periodic table, which provides a fundamental understanding of the chemical behavior of the elements. As mentioned in the introduction, the periodic table explains how more than 100 elements can be formed from three particles, the electron, the proton, and the neutron. The table of nuclides, part of which is shown in Table 44.2, contains hundreds of nuclides, but all can be built from protons and neutrons.

The number of particles observed by particle physicists is in the hundreds. Is it possible that a small number of entities exist from which all these particles can be built? Taking a hint from the success of the periodic table and the table of nuclides, let’s explore the historical search for patterns among the particles.

Many classification schemes have been proposed for grouping particles into families. Consider, for instance, the baryons listed in Table 46.2 that have spins of \( \frac{1}{2} \): p, n, \( \Lambda^0 \), \( \Sigma^+ \), \( \Sigma^0 \), \( \Sigma^- \), \( \Xi^0 \), and \( \Xi^- \). If we plot strangeness versus charge for these baryons using a sloping coordinate system as in Figure 46.8a, a fascinating pattern is observed: six of the baryons form a hexagon, and the remaining two are at the hexagon’s center.

As a second example, consider the following nine spin-zero mesons listed in Table 46.2: \( \pi^+ \), \( \pi^0 \), \( \pi^- \), \( K^+ \), \( K^- \), \( \eta \), \( \eta' \), and the antiparticle \( \bar{K}^0 \). Figure 46.8b is a plot of strangeness versus charge for this family. Again, a hexagonal pattern emerges. In this case, each particle on the perimeter of the hexagon lies opposite its antiparticle and the remaining three (which form their own antiparticles) are at the center of the hexagon. These and related symmetric patterns were developed independently in 1961 by Murray Gell-Mann and Yuval Ne’eman (1925–2006). Gell-Mann called the patterns the eightfold way, after the eightfold path to nirvana in Buddhism.

Groups of baryons and mesons can be displayed in many other symmetric patterns within the framework of the eightfold way. For example, the family of spin-\( \frac{3}{2} \) baryons known in 1961 contains nine particles arranged in a pattern like that of the pins in a bowling alley as in Figure 46.9. (The particles \( \Sigma^{*+} \), \( \Sigma^{*0} \), \( \Sigma^{*-} \), \( \Xi^{*0} \), \( \Xi^{*-} \), \( \Omega^- \).)

The absence of a particle in the bottom position was evidence of a new particle yet to be discovered, the \( \Omega^- \).

Figure 46.8 (a) The hexagonal eightfold-way pattern for the eight spin-\( \frac{1}{2} \) baryons. This strangeness-versus-charge plot uses a sloping axis for charge number \( Q \) and a horizontal axis for strangeness \( S \).
(b) The eightfold-way pattern for the nine spin-zero mesons.

Figure 46.9 The pattern for the higher-mass, spin-\( \frac{3}{2} \) baryons known at the time the pattern was proposed.
and $\Xi^-$ are excited states of the particles $\Sigma^+$, $\Sigma^0$, $\Sigma^-$, $\Xi^0$, and $\Xi^-$. In these higher-energy states, the spins of the three quarks—see Section 46.8—making up the particle are aligned so that the total spin of the particle is $\frac{3}{2}$. When this pattern was proposed, an empty spot occurred in it (at the bottom position), corresponding to a particle that had never been observed. Gell-Mann predicted that the missing particle, which he called the omega minus ($\Omega^-$), should have spin $\frac{3}{2}$, charge $-\frac{1}{3}$, strangeness $-3$, and rest energy of approximately 1680 MeV. Shortly thereafter, in 1964, scientists at the Brookhaven National Laboratory found the missing particle through careful analyses of bubble-chamber photographs (Fig. 46.10) and confirmed all its predicted properties.

The prediction of the missing particle in the eightfold way has much in common with the prediction of missing elements in the periodic table. Whenever a vacancy occurs in an organized pattern of information, experimentalists have a guide for their investigations.

### 46.8 Quarks

As mentioned earlier, leptons appear to be truly elementary particles because there are only a few types of them, and experiments indicate that they have no measurable size or internal structure. Hadrons, on the other hand, are complex particles having size and structure. The existence of the strangeness–charge patterns of the eightfold way suggests that hadrons have substructure. Furthermore, hundreds of types of hadrons exist and many decay into other hadrons.

#### The Original Quark Model

In 1963, Gell-Mann and George Zweig (b. 1937) independently proposed a model for the substructure of hadrons. According to their model, all hadrons are composed of two or three elementary constituents called quarks. (Gell-Mann borrowed the word quark from the passage “Three quarks for Muster Mark” in James Joyce’s *Finnegans Wake*. In Zweig’s model, he called the constituents “aces.”) The model has three types of quarks, designated by the symbols u, d, and s, that are given the arbitrary names up, down, and strange. The various types of quarks are called flavors. Figure 46.11 is a pictorial representation of the quark compositions of several hadrons.
An unusual property of quarks is that they carry a fractional electric charge. The u, d, and s quarks have charges of $+\frac{2}{3}e$, $-\frac{1}{3}e$, and $-\frac{2}{3}e$, respectively, where $e$ is the elementary charge $1.60 \times 10^{-19}$ C. These and other properties of quarks and antiquarks are given in Table 46.3. Quarks have spin $\frac{1}{2}$, which means that all quarks are fermions, defined as any particle having half-integral spin, as pointed out in Section 43.8. As Table 46.3 shows, associated with each quark is an antiquark of opposite charge, baryon number, and strangeness.

The compositions of all hadrons known when Gell-Mann and Zweig presented their model can be completely specified by three simple rules:

- A meson consists of one quark and one antiquark, giving it a baryon number of 0, as required.
- A baryon consists of three quarks.
- An antibaryon consists of three antiquarks.

The theory put forth by Gell-Mann and Zweig is referred to as the original quark model.

Quick Quiz 46.5 Using a coordinate system like that in Figure 46.8, draw an eightfold-way diagram for the three quarks in the original quark model.

Charm and Other Developments

Although the original quark model was highly successful in classifying particles into families, some discrepancies occurred between its predictions and certain experimental decay rates. Consequently, several physicists proposed a fourth quark flavor in 1967. They argued that if four types of leptons exist (as was thought at the time), there should also be four flavors of quarks because of an underlying symmetry in nature. The fourth quark, designated $c$, was assigned a property called charm. A *charmed* quark has charge $+\frac{2}{3}e$, just as the up quark does, but its charm distinguishes it from the other three quarks. This introduces a new quantum number $C$, representing charm. The new quark has charm $C = +1$, its antiquark has charm of $C = -1$, and all other quarks have $C = 0$. Charm, like strangeness, is conserved in strong and electromagnetic interactions but not in weak interactions.
Evidence that the charmed quark exists began to accumulate in 1974, when a heavy meson called the \( J/\Psi \) particle (or simply \( \Psi \), Greek letter psi) was discovered independently by two groups, one led by Burton Richter (b. 1931) at the Stanford Linear Accelerator (SLAC), and the other led by Samuel Ting (b. 1936) at the Brookhaven National Laboratory. In 1976, Richter and Ting were awarded the Nobel Prize in Physics for this work. The \( J/\Psi \) particle does not fit into the three-quark model; instead, it has properties of a combination of the proposed charmed quark and its antiquark \((c\bar{c})\). It is much more massive than the other known mesons (~300 MeV/c^2), and its lifetime is much longer than the lifetimes of particles that interact via the strong force. Soon, related mesons were discovered, corresponding to such quark combinations as \( c\bar{d} \) and \( c\bar{d} \), all of which have great masses and long lifetimes. The existence of these new mesons provided firm evidence for the fourth quark flavor.

In 1975, researchers at Stanford University reported strong evidence for the tau (\( \tau \)) lepton, mass 1 784 MeV/c^2. This fifth type of lepton led physicists to propose that more flavors of quarks might exist, on the basis of symmetry arguments similar to those leading to the proposal of the charmed quark. These proposals led to more elaborate quark models and the prediction of two new quarks, \textbf{top} (\( t \)) and \textbf{bottom} (\( b \)). (Some physicists prefer \textit{truth} and \textit{beauty}.) To distinguish these quarks from the others, quantum numbers called \textit{topness} and \textit{bottomness} (with allowed values +1, 0, \(-1\)) were assigned to all quarks and antiquarks (see Table 46.3). In 1977, researchers at the Fermi National Laboratory, under the direction of Leon Lederman (b. 1922), reported the discovery of a very massive new meson \( Y \) (Greek letter upsilon), whose composition is considered to be \( b\bar{b} \), providing evidence for the bottom quark. In March 1995, researchers at Fermilab announced the discovery of the top quark (supposedly the last of the quarks to be found), which has a mass of 173 GeV/c^2.

Table 46.4 lists the quark compositions of mesons formed from the up, down, strange, charmed, and bottom quarks. Table 46.5 shows the quark combinations for the baryons listed in Table 46.2. Notice that only two flavors of quarks, \( u \) and \( d \), are contained in all hadrons encountered in ordinary matter (protons and neutrons).

Will the discoveries of elementary particles ever end? How many “building blocks” of matter actually exist? At present, physicists believe that the elementary particles in nature are six quarks and six leptons, together with their antiparticles, and the four field particles listed in Table 46.1. Table 46.6 lists the rest energies and charges of the quarks and leptons.

Despite extensive experimental effort, no isolated quark has ever been observed. Physicists now believe that at ordinary temperatures, quarks are permanently confined inside ordinary particles because of an exceptionally strong force that prevents them from escaping, called (appropriately) the \textbf{strong force}^3 (which we

---

4As a reminder, the original meaning of the term \textit{strong force} was the short-range attractive force between nucleons, which we have called the \textit{nuclear force}. The nuclear force between nucleons is a secondary effect of the strong force between quarks.
Multicolored Quarks

Introduction

Quark–gluon plasma

Current efforts are under way to form a quark–gluon plasma, a state of matter in which the quarks are freed from neutrons and protons. In 2000, scientists at CERN announced evidence for a quark–gluon plasma formed by colliding lead nuclei. In 2005, experiments at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven suggested the creation of a quark–gluon plasma. Neither laboratory has provided definitive data to verify the existence of a quark–gluon plasma. Experiments continue, and the ALICE project (A Large Ion Collider Experiment) at the Large Hadron Collider at CERN has joined the search.

Quick Quiz

46.6 Doubly charged baryons, such as the $D^{++}$, are known to exist.

True or False: Doubly charged mesons also exist.

Multicolored Quarks

Shortly after the concept of quarks was proposed, scientists recognized that certain particles had quark compositions that violated the exclusion principle. In Section 42.7, we applied the exclusion principle to electrons in atoms. The principle is more general, however, and applies to all particles with half-integral spin ($\frac{1}{2}, \frac{3}{2}$, etc.), which are collectively called fermions. Because all quarks are fermions having spin $\frac{1}{2}$, they are expected to follow the exclusion principle. One example of a particle that appears to violate the exclusion principle is the $V^-$ (sss) baryon, which contains three strange quarks having parallel spins, giving it a total spin of $\frac{3}{2}$. All three quarks have the same spin quantum number, in violation of the exclusion principle. Other examples of baryons made up of identical quarks having parallel spins are the $\Delta^+$ (uuu) and the $\Delta^-$ (ddu).

To resolve this problem, it was suggested that quarks possess an additional property called color charge. This property is similar in many respects to electric charge except that it occurs in six varieties rather than two. The colors assigned to quarks are red, green, and blue, and antiquarks have the colors antired, antigreen, and antiblue. Therefore, the colors red, green, and blue serve as the “quantum numbers” for the color of the quark. To satisfy the exclusion principle, the three quarks in any baryon must all have different colors. Look again at the quarks in the baryons in Figure 46.11 and notice the colors. The three colors “neutralize” to white.

Pitfall Prevention 46.3

Color Charge Is Not Really Color

The description of color for a quark has nothing to do with visual sensation from light. It is simply a convenient name for a property that is analogous to electric charge.
A quark and an antiquark in a meson must be of a color and the corresponding anticolor and will consequently neutralize to white, similar to the way electric charges $+1$ and $-1$ neutralize to zero net charge. (See the mesons in Fig. 46.11.) The apparent violation of the exclusion principle in the $\Omega^-$ baryon is removed because the three quarks in the particle have different colors.

The new property of color increases the number of quarks by a factor of 3 because each of the six quarks comes in three colors. Although the concept of color in the quark model was originally conceived to satisfy the exclusion principle, it also provided a better theory for explaining certain experimental results. For example, the modified theory correctly predicts the lifetime of the $\pi^0$ meson.

The theory of how quarks interact with each other is called quantum chromodynamics, or QCD, to parallel the name quantum electrodynamics (the theory of the electrical interaction between light and matter). In QCD, each quark is said to carry a color charge, in analogy to electric charge. The strong force between quarks is often called the color force. Therefore, the terms strong force and color force are used interchangeably.

In Section 46.1, we stated that the nuclear interaction between hadrons is mediated by massless field particles called gluons. As mentioned earlier, the nuclear force is actually a secondary effect of the strong force between quarks. The gluons are the mediators of the strong force. When a quark emits or absorbs a gluon, the quark’s color may change. For example, a blue quark that emits a gluon may become a red quark and a red quark that absorbs this gluon becomes a blue quark.

The color force between quarks is analogous to the electric force between charges: particles with the same color repel, and those with opposite colors attract. Therefore, two green quarks repel each other, but a green quark is attracted to an antigreen quark. The attraction between quarks of opposite color to form a meson ($q\bar{q}$) is indicated in Figure 46.12a. Differently colored quarks also attract one another, although with less intensity than the oppositely colored quark and antiquark. For example, a cluster of red, blue, and green quarks all attract one another to form a baryon as in Figure 46.12b. Therefore, every baryon contains three quarks of three different colors.

Although the nuclear force between two colorless hadrons is negligible at large separations, the net strong force between their constituent quarks is not exactly zero at small separations. This residual strong force is the nuclear force that binds protons and neutrons to form nuclei. It is similar to the force between two electric dipoles. Each dipole is electrically neutral. An electric field surrounds the dipoles, however, because of the separation of the positive and negative charges (see Section 23.6). As a result, an electric interaction occurs between the dipoles that is weaker than the force between single charges. In Section 43.1, we explored how this interaction results in the Van der Waals force between neutral molecules.

According to QCD, a more basic explanation of the nuclear force can be given in terms of quarks and gluons. Figure 46.13a shows the nuclear interaction between a neutron and a proton by means of Yukawa’s pion, in this case a $\pi^-$. This drawing differs from Figure 46.5a, in which the field particle is a $\pi^0$; there is no transfer of charge from one nucleon to the other in Figure 46.5a. In Figure 46.13a, the charged pion carries charge from one nucleon to the other, so the nucleons change identities, with the proton becoming a neutron and the neutron becoming a proton.
Let’s look at the same interaction from the viewpoint of the quark model, shown in Figure 46.13b. In this Feynman diagram, the proton and neutron are represented by their quark constituents. Each quark in the neutron and proton is continuously emitting and absorbing gluons. The energy of a gluon can result in the creation of quark–antiquark pairs. This process is similar to the creation of electron–positron pairs in pair production, which we investigated in Section 46.2. When the neutron and proton approach to within 1 fm of each other, these gluons and quarks can be exchanged between the two nucleons, and such exchanges produce the nuclear force. Figure 46.13b depicts one possibility for the process shown in Figure 46.13a. A down quark in the neutron on the right emits a gluon. The energy of the gluon is then transformed to create a \(u\)–\(\bar{u}\) pair. The \(u\) quark stays within the nucleon (which has now changed to a proton), and the recoiling \(d\) quark and the \(\bar{u}\) antiquark are transmitted to the proton on the left side of the diagram. Here the \(\bar{u}\) annihilates a \(u\) quark within the proton and the \(d\) is captured. The net effect is to change a \(u\) quark to a \(d\) quark, and the proton on the left has changed to a neutron.

As the \(d\) quark and \(\bar{u}\) antiquark in Figure 46.13b transfer between the nucleons, the \(d\) and \(\bar{u}\) exchange gluons with each other and can be considered to be bound to each other by means of the strong force. Looking back at Table 46.4, we see that this combination is a \(\pi^-\), or Yukawa’s field particle! Therefore, the quark model of interactions between nucleons is consistent with the pion-exchange model.

**46.10 The Standard Model**

Scientists now believe there are three classifications of truly elementary particles: leptons, quarks, and field particles. These three types of particles are further classified as either fermions or bosons. Quarks and leptons have spin \(\frac{1}{2}\) and hence are fermions, whereas the field particles have integral spin of 1 or higher and are bosons.

Recall from Section 46.1 that the weak force is believed to be mediated by the \(W^+\), \(W^-\), and \(Z^0\) bosons. These particles are said to have weak charge, just as quarks have color charge. Therefore, each elementary particle can have mass, electric charge, color charge, and weak charge. Of course, one or more of these could be zero.

In 1979, Sheldon Glashow (b. 1932), Abdus Salam (1926–1996), and Steven Weinberg (b. 1933) won the Nobel Prize in Physics for developing a theory that unifies the electromagnetic and weak interactions. This electroweak theory postulates that the weak and electromagnetic interactions have the same strength when the particles involved have very high energies. The two interactions are viewed as different manifestations of a single unifying electroweak interaction. The theory makes many concrete predictions, but perhaps the most spectacular is the prediction of
the masses of the W and Z particles at approximately 82 GeV/c² and 93 GeV/c², respectively. These predictions are close to the masses in Table 46.1 determined by experiment.

The combination of the electroweak theory and QCD for the strong interaction is referred to in high-energy physics as the **Standard Model**. Although the details of the Standard Model are complex, its essential ingredients can be summarized with the help of Fig. 46.14. (Although the Standard Model does not include the gravitational force at present, we include gravity in Fig. 46.14 because physicists hope to eventually incorporate this force into a unified theory.) This diagram shows that quarks participate in all the fundamental forces and that leptons participate in all except the strong force.

The Standard Model does not answer all questions. A major question still unanswered is why, of the two mediators of the electroweak interaction, the photon has no mass but the W and Z bosons do. Because of this mass difference, the electromagnetic and weak forces are quite distinct at low energies but become similar at very high energies, when the rest energy is negligible relative to the total energy. The behavior as one goes from high to low energies is called **symmetry breaking** because the forces are similar, or symmetric, at high energies but are very different at low energies. The nonzero rest energies of the W and Z bosons raise the question of the origin of particle masses. To resolve this problem, a hypothetical particle called the **Higgs boson**, which provides a mechanism for breaking the electroweak symmetry, has been proposed. The Standard Model modified to include the Higgs boson provides a logically consistent explanation of the massive nature of the W and Z bosons. In July 2012, announcements from the ATLAS (A Toroidal LHC Apparatus) and CMS (Compact Muon Solenoid) experiments at the Large Hadron Collider (LHC) at CERN claimed the discovery of a new particle having properties consistent with that of a Higgs boson. The mass of the particle is 125–127 GeV, within the range of predictions made from theoretical considerations using the Standard Model.

Because of the limited energy available in conventional accelerators using fixed targets, it is necessary to employ colliding-beam accelerators called **colliders**. The concept of colliders is straightforward. Particles that have equal masses and equal kinetic energies, traveling in opposite directions in an accelerator ring, collide head-on to produce the required reaction and form new particles. Because the total momentum of the interacting particles is zero, all their kinetic energy is available for the reaction.

Several colliders provided important data for understanding the Standard Model in the latter part of the 20th century and the first decade of the 21st century: the Large Electron–Positron (LEP) Collider and the Super Proton Synchrotron at CERN, the Stanford Linear Collider, and the Tevatron at the Fermi National Laboratory in Illinois. The Relativistic Heavy Ion Collider at Brookhaven National Laboratory is the sole remaining collider in operation in the United States. The Large Hadron Collider at CERN, which began collision operations in March 2010, has
46.11 The Cosmic Connection

In this section, we describe one of the most fascinating theories in all science—the Big Bang theory of the creation of the Universe—and the experimental evidence that supports it. This theory of cosmology states that the Universe had a beginning and furthermore that the beginning was so cataclysmic that it is impossible to look back beyond it. According to this theory, the Universe erupted from an infinitely dense singularity about 14 billion years ago. The first few moments after the Big Bang saw such extremely high energy that it is believed that all four interactions of physics were unified and all matter was contained in a quark–gluon plasma.

The evolution of the four fundamental forces from the Big Bang to the present is shown in Figure 46.16 (page 1470). During the first $10^{-43}$ s (the ultrahot epoch, $T \sim 10^{32}$ K), it is presumed the strong, electroweak, and gravitational forces were joined to form a completely unified force. In the first $10^{-35}$ s following the Big Bang (the hot epoch, $T \sim 10^{29}$ K), symmetry breaking occurred for gravity while the strong and electroweak forces remained unified. It was a period when particle energies were so great ($\sim 10^{16}$ GeV) that very massive particles as well as quarks, leptons, and their antiparticles existed. Then, after $10^{-35}$ s, the Universe rapidly expanded and cooled (the warm epoch, $T \sim 10^{29}$ to $10^{15}$ K) and the strong and electroweak forces parted company. As the Universe continued to cool, the electroweak force split into the weak force and the electromagnetic force approximately $10^{-10}$ s after the Big Bang.

After a few minutes, protons and neutrons condensed out of the plasma. For half an hour, the Universe underwent thermonuclear fusion, exploding as a hydrogen bomb and producing most of the helium nuclei that now exist. The Universe continued to expand, and its temperature dropped. Until about 700 000 years after the Big Bang, the Universe was dominated by radiation. Energetic radiation prevented matter from forming single hydrogen atoms because photons would instantly ionize any atoms that happened to form. Photons experienced continuous Compton scattering from the vast numbers of free electrons, resulting in a Universe that was opaque to radiation. By the time the Universe was about 700 000 years old, it had taken the lead in particle studies due to its extremely high energy capabilities. The expected upper limit for the LHC is a center-of-mass energy of 14 TeV. (See page 868 for a photo of a magnet used by the LHC.)

In addition to increasing energies in modern accelerators, detection techniques have become increasingly sophisticated. We saw simple bubble-chamber photographs earlier in this chapter that required hours of analysis by hand. Figure 46.15 shows a complex set of tracks from a collision of gold nuclei.

Figure 46.15 A shower of particle tracks from a head-on collision of gold nuclei, each moving with energy 100 GeV. This collision occurred at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory and was recorded with the STAR (Solenoidal Tracker at RHIC) detector. The tracks represent many fundamental particles arising from the energy of the collision.
Chapter 46  Particle Physics and Cosmology

Gravitational force splits off from the strong and electroweak forces.
The Universe expands rapidly.
The strong and electroweak forces split.
The weak and electromagnetic forces split.
The expansion appears to accelerate.

The Big Bang occurs. All forces are unified.
The Universe consists of quarks and leptons.
Protons and neutrons can form.
Nuclei can form.
Atoms can form.

Figure 46.16  A brief history of the Universe from the Big Bang to the present. The four forces became distinguishable during the first nanosecond. Following that, all the quarks combined to form particles that interact via the nuclear force. The leptons, however, remained separate and to this day exist as individual, observable particles.

expanded and cooled to approximately 3000 K and protons could bind to electrons to form neutral hydrogen atoms. Because of the quantized energies of the atoms, far more wavelengths of radiation were not absorbed by atoms than were absorbed, and the Universe suddenly became transparent to photons. Radiation no longer dominated the Universe, and clumps of neutral matter steadily grew: first atoms, then molecules, gas clouds, stars, and finally galaxies.

Observation of Radiation from the Primordial Fireball

In 1965, Arno A. Penzias (b. 1933) and Robert W. Wilson (b. 1936) of Bell Laboratories were testing a sensitive microwave receiver and made an amazing discovery. A pesky signal producing a faint background hiss was interfering with their satellite communications experiments. The microwave horn that served as their receiving antenna is shown in Figure 46.17. Evicting a flock of pigeons from the 20-ft horn and cooling the microwave detector both failed to remove the signal.

The intensity of the detected signal remained unchanged as the antenna was pointed in different directions. That the radiation had equal strengths in all directions suggested that the entire Universe was the source of this radiation. Ultimately, it became clear that they were detecting microwave background radiation (at a wavelength of 7.35 cm), which represented the leftover “glow” from the Big Bang. Through a casual conversation, Penzias and Wilson discovered that a group at Princeton University had predicted the residual radiation from the Big Bang and were planning an experiment to attempt to confirm the theory. The excitement in the scientific community was high when Penzias and Wilson announced that they had already observed an excess microwave background compatible with a 3-K
blackbody source, which was consistent with the predicted temperature of the Universe at this time after the Big Bang.

Because Penzias and Wilson made their measurements at a single wavelength, they did not completely confirm the radiation as 3-K blackbody radiation. Subsequent experiments by other groups added intensity data at different wavelengths as shown in Figure 46.18. The results confirm that the radiation is that of a black body at 2.7 K. This figure is perhaps the most clear-cut evidence for the Big Bang theory. The 1978 Nobel Prize in Physics was awarded to Penzias and Wilson for this most important discovery.

In the years following Penzias and Wilson’s discovery, other researchers made measurements at different wavelengths. In 1989, the COBE (COsmic Background Explorer) satellite was launched by NASA and added critical measurements at wavelengths below 0.1 cm. The results of these measurements led to a Nobel Prize in Physics for the principal investigators in 2006. Several data points from COBE are shown in Figure 46.18. The Wilkinson Microwave Anisotropy Probe, launched in June 2001, exhibits data that allow observation of temperature differences in the cosmos in the microkelvin range. Ongoing observations are also being made from Earth-based facilities, associated with projects such as QUaD, Qubic, and the South Pole Telescope. In addition, the Planck satellite was launched in May 2009 by the European Space Agency. This space-based observatory has been measuring the cosmic background radiation with higher sensitivity than the Wilkinson probe. The series of measurements taken since 1965 are consistent with thermal radiation associated with a temperature of 2.7 K. The whole story of the cosmic temperature is a remarkable example of science at work: building a model, making a prediction, taking measurements, and testing the measurements against the predictions.

**Other Evidence for an Expanding Universe**

The Big Bang theory of cosmology predicts that the Universe is expanding. Most of the key discoveries supporting the theory of an expanding Universe were made in the 20th century. Vesto Melvin Slipher (1875–1969), an American astronomer, reported in 1912 that most galaxies are receding from the Earth at speeds up to several million miles per hour. Slipher was one of the first scientists to use Doppler shifts (see Section 17.4) in spectral lines to measure galaxy velocities.

In the late 1920s, Edwin P. Hubble (1889–1953) made the bold assertion that the whole Universe is expanding. From 1928 to 1936, until they reached the limits of the 100-inch telescope, Hubble and Milton Humason (1891–1972) worked at Mount Wilson in California to prove this assertion. The results of that work and of its continuation with the use of a 200-inch telescope in the 1940s showed that the speeds...
at which galaxies are receding from the Earth increase in direct proportion to their distance $R$ from us. This linear relationship, known as Hubble’s law, may be written

Hubble’s law

$$v = HR$$

(46.4)

where $H$, called the Hubble constant, has the approximate value

$$H \approx 22 \times 10^{-3} \text{ m/(s \cdot ly)}$$

Example 46.5  Recession of a Quasar  AM

A quasar is an object that appears similar to a star and is very distant from the Earth. Its speed can be determined from Doppler-shift measurements in the light it emits. A certain quasar recedes from the Earth at a speed of $0.55c$. How far away is it?

Solution

Conceptualize A common mental representation for the Hubble law is that of raisin bread cooking in an oven. Imagine yourself at the center of the loaf of bread. As the entire loaf of bread expands upon heating, raisins near you move slowly with respect to you. Raisins far away from you on the edge of the loaf move at a higher speed.

Categorize We use a concept developed in this section, so we categorize this example as a substitution problem.

Find the distance through Hubble’s law:

$$R = \frac{v}{H} = \frac{(0.55)(3.00 \times 10^9 \text{ m/s})}{22 \times 10^{-3} \text{ m/(s \cdot ly)}} = 7.5 \times 10^9 \text{ ly}$$

What If? Suppose the quasar has moved at this speed ever since the Big Bang. With this assumption, estimate the age of the Universe.

Answer Let’s approximate the distance from the Earth to the quasar as the distance the quasar has moved from the singularity since the Big Bang. We can then find the time interval from the particle under constant speed model:

$$\Delta t = \frac{d}{v} = \frac{R}{v} = \frac{1}{H} \approx 14 \text{ billion years},$$

which is in approximate agreement with other calculations.

Will the Universe Expand Forever?

In the 1950s and 1960s, Allan R. Sandage (1926–2010) used the 200-inch telescope at Mount Palomar to measure the speeds of galaxies at distances of up to 6 billion light-years away from the Earth. These measurements showed that these very distant galaxies were moving approximately 10 000 km/s faster than Hubble’s law predicted. According to this result, the Universe must have been expanding more rapidly 1 billion years ago, and consequently we conclude from these data that the expansion rate is slowing. Today, astronomers and physicists are trying to determine the rate of expansion. If the average mass density of the Universe is less than some critical value $\rho_c$, the galaxies will slow in their outward rush but still escape to infinity. If the average density exceeds the critical value, the expansion will eventually stop and contraction will begin, possibly leading to a superdense state followed by another expansion. In this scenario, we have an oscillating Universe.

Example 46.6  The Critical Density of the Universe  AM

(A) Starting from energy conservation, derive an expression for the critical mass density of the Universe $\rho_c$, in terms of the Hubble constant $H$ and the universal gravitational constant $G$.

6The data at large distances have large observational uncertainties and may be systematically in error from effects such as abnormal brightness in the most distant visible clusters.
Conceptualize: Figure 46.19 shows a large section of the Universe, contained within a sphere of radius $R$. The total mass in this volume is the mass of a galaxy of mass that has a speed at a distance from the center of the sphere escapes to infinity (at which its speed approaches zero) if the sum of its kinetic energy and the gravitational potential energy of the system is zero.

Categorize: The Universe may be infinite in spatial extent, but Gauss’s law for gravitation (an analog to Gauss’s law for electric fields in Chapter 24) implies that only the mass inside the sphere contributes to the gravitational potential energy of the galaxy–sphere system. Therefore, we categorize this problem as one in which we apply Gauss’s law for gravitation. We model the sphere in Figure 46.19 and the escaping galaxy as an isolated system for energy.

Analyze: Write the appropriate reduction of Equation 8.2, assuming that the galaxy leaves the spherical volume while moving at the escape speed:

$$-mv = \frac{GmM}{bR}$$

Substitute for the mass contained within the sphere the product of the critical density and the volume of the sphere:

$$-mv = \frac{G\rho V}{bR}$$

Solve for the critical density:

From Hubble’s law, substitute for the ratio $H$:

$$(1) \quad \frac{H}{v} = \frac{1}{b}$$

(B) Estimate a numerical value for the critical density in grams per cubic centimeter.

Solve 10: In Equation (1), substitute numerical values for $H$ and $v$:

$$\frac{H}{v} = \frac{1}{b}$$

Reconcile the units by converting light-years to meters:

$$8.7 \times 10^{10} \text{ ly} = 9.46 \times 10^{15} \text{ m}$$

Finalize: Because the mass of a hydrogen atom is $1.67 \times 10^{-24} \text{ g}$, this value of $\rho$ corresponds to $6 \times 10^3$ hydrogen atoms per cubic centimeter or $6$ atoms per cubic meter.

Missing Mass in the Universe?

The luminous matter in galaxies averages out to a Universe density of about $0.1 \text{ g/cm}^3$. The radiation in the Universe has a mass equivalent of approximately $2\%$ of the luminous matter. The total mass of all nonluminous matter (such as interstellar gas and black holes) may be estimated from the speeds of galaxies orbiting each other in a cluster. The higher the galaxy speeds, the more mass in the cluster. Measurements on the Coma cluster of galaxies indicate, surprisingly,
that the amount of nonluminous matter is 20 to 30 times the amount of luminous matter present in stars and luminous gas clouds. Yet even this large, invisible component of dark matter (see Section 13.6), if extrapolated to the Universe as a whole, leaves the observed mass density a factor of 10 less than \( \rho \), calculated in Example 46.6. The deficit, called missing mass, has been the subject of intense theoretical and experimental work, with exotic particles such as axions, photinos, and superstring particles suggested as candidates for the missing mass. Some researchers have made the more mundane proposal that the missing mass is present in neutrinos. In fact, neutrinos are so abundant that a tiny neutrino rest energy on the order of only 20 eV would furnish the missing mass and “close” the Universe. Current experiments designed to measure the rest energy of the neutrino will have an effect on predictions for the future of the Universe.

**Mysterious Energy in the Universe?**

A surprising twist in the story of the Universe arose in 1998 with the observation of a class of supernovae that have a fixed absolute brightness. By combining the apparent brightness and the redshift of light from these explosions, their distance and speed of recession from the Earth can be determined. These observations led to the conclusion that the expansion of the Universe is not slowing down, but is accelerating! Observations by other groups also led to the same interpretation.

To explain this acceleration, physicists have proposed dark energy, which is energy possessed by the vacuum of space. In the early life of the Universe, gravity dominated over the dark energy. As the Universe expanded and the gravitational force between galaxies became smaller because of the great distances between them, the dark energy became more important. The dark energy results in an effective repulsive force that causes the expansion rate to increase.\(^7\)

Although there is some degree of certainty about the beginning of the Universe, we are uncertain about how the story will end. Will the Universe keep on expanding forever, or will it someday collapse and then expand again, perhaps in an endless series of oscillations? Results and answers to these questions remain inconclusive, and the exciting controversy continues.

### 46.12 Problems and Perspectives

While particle physicists have been exploring the realm of the very small, cosmologists have been exploring cosmic history back to the first microsecond of the Big Bang. Observation of the events that occur when two particles collide in an accelerator is essential for reconstructing the early moments in cosmic history. For this reason, perhaps the key to understanding the early Universe is to first understand the world of elementary particles. Cosmologists and physicists now find that they have many common goals and are joining hands in an attempt to understand the physical world at its most fundamental level.

Our understanding of physics at short distances is far from complete. Particle physics is faced with many questions. Why does so little antimatter exist in the Universe? Is it possible to unify the strong and electroweak theories in a logical and consistent manner? Why do quarks and leptons form three similar but distinct families? Are muons the same as electrons apart from their difference in mass, or do they have other subtle differences that have not been detected? Why are some particles charged and others neutral? Why do quarks carry a fractional charge? What determines the masses of the elementary constituents of matter? Can isolated quarks exist? Why do electrons and protons have exactly the same magnitude of

problems and perspectives

charge when one is a truly fundamental particle and the other is built from smaller particles?

An important and obvious question that remains is whether leptons and quarks have an underlying structure. If they do, we can envision an infinite number of deeper structure levels. If leptons and quarks are indeed the ultimate constituents of matter, however, scientists hope to construct a final theory of the structure of matter, just as Einstein dreamed of doing. This theory, whimsically called the Theory of Everything, is a combination of the Standard Model and a quantum theory of gravity.

String Theory: A New Perspective

Let’s briefly discuss one current effort at answering some of these questions by proposing a new perspective on particles. While reading this book, you may recall starting off with the particle model in Chapter 2 and doing quite a bit of physics with it. In Chapter 16, we introduced the wave model, and there was more physics to be investigated via the properties of waves. We used a wave model for light in Chapter 35; in Chapter 40, however, we saw the need to return to the particle model for light.

Furthermore, we found that material particles had wave-like characteristics. The quantum particle model discussed in Chapter 40 allowed us to build particles out of waves, suggesting that a wave is the fundamental entity. In the current Chapter 46, however, we introduced elementary particles as the fundamental entities. It seems as if we cannot make up our mind! In this final section, we discuss a current research effort to build particles out of waves and vibrations on strings!

String theory is an effort to unify the four fundamental forces by modeling all particles as various quantized vibrational modes of a single entity, an incredibly small string. The typical length of such a string is on the order of $10^{-16}$ m, called the Planck length. We have seen quantized modes before in the frequencies of vibrating guitar strings in Chapter 18 and the quantized energy levels of atoms in Chapter 42. In string theory, each quantized mode of vibration of the string corresponds to a different elementary particle in the Standard Model.

One complicating factor in string theory is that it requires space–time to have ten dimensions. Despite the theoretical and conceptual difficulties in dealing with ten dimensions, string theory holds promise in incorporating gravity with the other forces. Four of the ten dimensions—three space dimensions and one time dimension—are visible to us. The other six are said to be compactified; that is, the six dimensions are curled up so tightly that they are not visible in the macroscopic world.

As an analogy, consider a soda straw. You can build a soda straw by cutting a rectangular piece of paper (Fig. 46.20a), which clearly has two dimensions, and rolling it into a small tube (Fig. 46.20b). From far away, the soda straw looks like a one-dimensional straight line. The second dimension has been curled up and is not visible. String theory claims that six space–time dimensions are curled up in an analogous way, with the curling being on the size of the Planck length and impossible to see from our viewpoint.

Another complicating factor with string theory is that it is difficult for string theorists to guide experimentalists as to what to look for in an experiment. The

![Figure 46.20](a) A piece of paper is cut into a rectangular shape. (b) The paper is rolled up into a soda straw.
Planck length is so small that direct experimentation on strings is impossible. Until the theory has been further developed, string theorists are restricted to applying the theory to known results and testing for consistency.

One of the predictions of string theory, called supersymmetry, or SUSY, suggests that every elementary particle has a superpartner that has not yet been observed. It is believed that supersymmetry is a broken symmetry (like the broken electroweak symmetry at low energies) and the masses of the superpartners are above our current capabilities of detection by accelerators. Some theorists claim that the mass of superpartners is the missing mass discussed in Section 46.11. Keeping with the whimsical trend in naming particles and their properties, superpartners are given names such as the squark (the superpartner to a quark), the selectron (electron), and the gluino (gluon).

Other theorists are working on M-theory, which is an eleven-dimensional theory based on membranes rather than strings. In a way reminiscent of the correspondence principle, M-theory is claimed to reduce to string theory if one compactifies from eleven dimensions to ten dimensions.

The questions listed at the beginning of this section go on and on. Because of the rapid advances and new discoveries in the field of particle physics, many of these questions may be resolved in the next decade and other new questions may emerge.

Summary

Concepts and Principles

Before quark theory was developed, the four fundamental forces in nature were identified as nuclear, electromagnetic, weak, and gravitational. All the interactions in which these forces take part are mediated by field particles. The electromagnetic interaction is mediated by photons; the weak interaction is mediated by the W± and Z0 bosons; the gravitational interaction is mediated by gravitons; and the nuclear interaction is mediated by gluons.

Particles other than field particles are classified as hadrons or leptons. Hadrons interact via all four fundamental forces. They have size and structure and are not elementary particles. There are two types, baryons and mesons. Baryons, which generally are the most massive particles, have nonzero baryon number and a spin of $\frac{1}{2}$ or $\frac{3}{2}$. Mesons have baryon number zero and either zero or integral spin.

In all reactions and decays, quantities such as energy, linear momentum, angular momentum, electric charge, baryon number, and lepton number are strictly conserved. Certain particles have properties called strangeness and charm. These unusual properties are conserved in all decays and nuclear reactions except those that occur via the weak force.

A charged particle and its antiparticle have the same mass but opposite charge, and other properties will have opposite values, such as lepton number and baryon number. It is possible to produce particle–antiparticle pairs in nuclear reactions if the available energy is greater than $2mc^2$, where $m$ is the mass of the particle (or antiparticle).

Leptons have no structure or size and are considered truly elementary. They interact only via the weak, gravitational, and electromagnetic forces. Six types of leptons exist: the electron $e^-$, the muon $\mu^-$, and the tau $\tau^-$, and their neutrinos $\nu_e$, $\bar{\nu}_\mu$, and $\bar{\nu}_\tau$.

In elementary particle physics, theorists have postulated that all hadrons are composed of smaller units known as quarks, and experimental evidence agrees with this model. Quarks have fractional electric charge and come in six flavors: (u) up, (d) down, (s) strange, (c) charmed, (t) top, and (b) bottom. Each baryon contains three quarks, and each meson contains one quark and one antiquark.
According to the theory of quantum chromodynamics, quarks have a property called color; the force between quarks is referred to as the strong force or the color force. The strong force is now considered to be a fundamental force. The nuclear force, which was originally considered to be fundamental, is now understood to be a secondary effect of the strong force due to gluon exchanges between hadrons.

The background microwave radiation discovered by Penzias and Wilson strongly suggests that the Universe started with a Big Bang about 14 billion years ago. The background radiation is equivalent to that of a black body at 3 K. Various astronomical measurements strongly suggest that the Universe is expanding. According to Hubble’s law, distant galaxies are receding from the Earth at a speed \( v = HR \), where \( H \) is the Hubble constant, \( H = 22 \times 10^{-5} \text{ m/s \cdot yr} \), and \( R \) is the distance from the Earth to the galaxy.

### Objective Questions

1. What interactions affect protons in an atomic nucleus? More than one answer may be correct. (a) the nuclear interaction (b) the weak interaction (c) the electromagnetic interaction (d) the gravitational interaction

2. In one experiment, two balls of clay of the same mass travel with the same speed \( v \) toward each other. They collide head-on and come to rest. In a second experiment, two clay balls of the same mass are again used. One ball hangs at rest, suspended from the ceiling by a thread. The second ball is fired toward the first at speed \( v \), to collide, stick to the first ball, and continue to move forward. Is the kinetic energy that is transformed into internal energy in the first experiment (a) one-fourth as much as in the second experiment, (b) one-half as much as in the second experiment, (c) the same as in the second experiment, (d) twice as much as in the second experiment, or (e) four times as much as in the second experiment?

3. The \( \Omega^- \) particle is a baryon with spin \( \frac{3}{2} \). Does the \( \Omega^- \) particle have (a) three possible spin states in a magnetic field, (b) four possible spin states, (c) three times the charge of a spin \( \frac{1}{2} \) particle, or (d) three times the mass of a spin \( \frac{1}{2} \) particle, or (e) are none of those choices correct?

4. Which of the following field particles mediates the strong force? (a) photon (b) gluon (c) graviton (d) \( W^\pm \) and \( Z \) bosons (e) none of those field particles

5. An isolated stationary muon decays into an electron, an electron antineutrino, and a muon neutrino. Is the total kinetic energy of these three particles (a) zero, (b) small, or (c) large compared to their rest energies, or (d) none of those choices are possible?

6. Define the average density of the solar system \( \rho_{SS} \) as the total mass of the Sun, planets, satellites, rings, asteroids, icy outliers, and comets, divided by the volume of a sphere around the Sun large enough to contain all these objects. The sphere extends about halfway to the nearest star, with a radius of approximately \( 2 \times 10^{10} \text{ m} \), about two light-years. How does this average density of the solar system compare with the critical density \( \rho_c \) required for the Universe to stop its Hubble’s-law expansion? (a) \( \rho_{SS} \) is much greater than \( \rho_c \). (b) \( \rho_{SS} \) is approximately or precisely equal to \( \rho_c \). (c) \( \rho_{SS} \) is much less than \( \rho_c \). (d) It is impossible to determine.

7. When an electron and a positron meet at low speed in empty space, they annihilate each other to produce two 0.511-MeV gamma rays. What law would be violated if they produced one gamma ray with an energy of 1.02 MeV? (a) conservation of energy (b) conservation of momentum (c) conservation of charge (d) conservation of baryon number (e) conservation of electron lepton number

8. Place the following events into the correct sequence from the earliest in the history of the Universe to the latest. (a) Neutral atoms form. (b) Protons and neutrons are no longer annihilated as fast as they form. (c) The Universe is a quark–gluon soup. (d) The Universe is like the core of a normal star today, forming helium by nuclear fusion. (e) The Universe is like the surface of a hot star today, consisting of a plasma of ionized atoms. (f) Polyatomic molecules form. (g) Solid materials form.

### Conceptual Questions

1. The W and Z bosons were first produced at CERN in 1983 by causing a beam of protons and a beam of antiprotons to meet at high energy. Why was this discovery important?

2. What are the differences between hadrons and leptons?

3. Neutral atoms did not exist until hundreds of thousands of years after the Big Bang. Why?
4. Describe the properties of baryons and mesons and the important differences between them.

5. The $\Xi^0$ particle decays by the weak interaction according to the decay mode $\Xi^0 \rightarrow \Lambda^0 + \pi^0$. Would you expect this decay to be fast or slow? Explain.

6. In the theory of quantum chromodynamics, quarks come in three colors. How would you justify the statement that “all baryons and mesons are colorless”?

7. An antibaryon interacts with a meson. Can a baryon be produced in such an interaction? Explain.

9. How many quarks are in each of the following: (a) a baryon, (b) an antibaryon, (c) a meson, (d) an antimeson? (e) How do you explain that baryons have half-integral spins, whereas mesons have spins of 0 or 1?

10. Are the laws of conservation of baryon number, lepton number, and strangeness based on fundamental properties of nature (as are the laws of conservation of momentum and energy, for example)? Explain.

11. Name the four fundamental interactions and the field particle that mediates each.

12. How did Edwin Hubble determine in 1928 that the Universe is expanding?

13. Kaons all decay into final states that contain no protons or neutrons. What is the baryon number for kaons?

**Problems**

Section 46.1 The Fundamental Forces in Nature

Section 46.2 Positrons and Other Antiparticles

1. Model a penny as 3.10 g of pure copper. Consider an anti-penny minted from 3.10 g of copper anti-atoms, each with 29 positrons in orbit around a nucleus comprising 29 antiprotons and 34 or 36 antineutrons. (a) Find the energy released if the two coins collide. (b) Find the value of this energy at the unit price of $0.11/kWh, a representative retail rate for energy from the electric company.

2. Two photons are produced when a proton and an antiproton annihilate each other. In the reference frame in which the center of mass of the proton–antiproton system is stationary, what are (a) the minimum frequency and (b) the corresponding wavelength of each photon?

3. A photon produces a proton–antiproton pair according to the reaction $\gamma \rightarrow p + \bar{p}$. (a) What is the minimum possible frequency of the photon? (b) What is its wavelength?

4. At some time in your life, you may find yourself in a hospital to have a PET, or positron-emission tomography, scan. In the procedure, a radioactive element that undergoes $e^-$ decay is introduced into your body. The equipment detects the gamma rays that result from pair annihilation when the emitted positron encounters an electron in your body's tissue. During such a scan, suppose you receive an injection of glucose containing on the order of $10^{10}$ atoms of $^{14}$O, with half-life 70.6 s. Assume the oxygen remaining after 5 min is uniformly distributed through 2 L of blood. What is then the order of magnitude of the oxygen atoms' activity in 1 cm$^3$ of the blood?

5. A photon with an energy $E_\gamma = 2.09$ GeV creates a proton–antiproton pair in which the proton has a kinetic energy of 95.0 MeV. What is the kinetic energy of the antiproton? Note: $m_p c^2 = 938.3$ MeV.

Section 46.3 Mesons and the Beginning of Particle Physics

6. One mediator of the weak interaction is the $Z^0$ boson, with mass 91 GeV/c$^2$. Use this information to find the order of magnitude of the range of the weak interaction.

7. (a) Prove that the exchange of a virtual particle of mass $m$ can be associated with a force with a range given by $d = \frac{1}{4\pi\hbar^2} = \frac{98.7}{m_c^2}$, where $d$ is in nanometers and $m_c^2$ is in electron volts.

(b) State the pattern of dependence of the range on the mass. (c) What is the range of the force that might be produced by the virtual exchange of a proton?
Section 46.4 Classification of Particles

Section 46.5 Conservation Laws

8. The first of the following two reactions can occur, but the second cannot. Explain.
   \[ K^0 \rightarrow \pi^+ + \pi^- \] (can occur)
   \[ \Lambda^0 \rightarrow \pi^+ + \pi^- \] (cannot occur)

9. A neutral pion at rest decays into two photons according to \( \pi^0 \rightarrow \gamma + \gamma \). Find the (a) energy, (b) momentum, and (c) frequency of each photon.

10. When a high-energy proton or pion traveling near the speed of light collides with a nucleus, it travels an average distance of \( 3 \times 10^{-15} \) m before interacting. From this information, find the order of magnitude of the time interval required for the strong interaction to occur.

11. Each of the following reactions is forbidden. Determine what conservation laws are violated for each reaction.
   (a) \( p + \bar{p} \rightarrow \mu^+ + e^- \)
   (b) \( \pi^- + p \rightarrow p + \pi^- \)
   (c) \( p + p \rightarrow p + p + n \)
   (d) \( \gamma + p \rightarrow n + \pi^0 \)
   (e) \( n + p \rightarrow n + e^+ \)

12. (a) Show that baryon number and charge are conserved in the following reactions of a pion with a proton:
    (1) \( \pi^+ + p \rightarrow K^+ + \Sigma^+ \)
    (2) \( \pi^+ + p \rightarrow \pi^+ + \Sigma^+ \)
    (b) The first reaction is observed, but the second never occurs. Explain.

13. The following reactions or decays involve one or more neutrinos. In each case, supply the missing neutrino (\( \nu_e, \nu_\mu, \) or \( \nu_\tau \)) or antineutrino.
   (a) \( \pi^- \rightarrow \mu^- + ? \)  (b) \( K^- \rightarrow \mu^- + ? \)
   (c) \( ? + p \rightarrow n + e^+ \)  (d) \( ? + n \rightarrow p + e^- \)
   (e) \( ? + n \rightarrow p + \mu^- \)  (f) \( \mu^- \rightarrow e^- + ? + ? \)

14. Determine the type of neutrino or antineutrino involved in each of the following processes.
   (a) \( \pi^+ \rightarrow \pi^0 + e^+ + ? \)  (b) \( ? + p \rightarrow \mu^- + p + \pi^+ \)
   (c) \( \Lambda^0 \rightarrow p + \mu^- + ? \)  (d) \( \tau^+ \rightarrow \mu^+ + ? + ? \)

15. Determine which of the following reactions can occur. For those that cannot occur, determine the conservation law (or laws) violated.
   (a) \( p \rightarrow \pi^+ + \pi^0 \)  (b) \( p + p \rightarrow p + p + \pi^0 \)
   (c) \( p + p \rightarrow p + \pi^+ \)  (d) \( \pi^+ \rightarrow \mu^+ + \nu_\mu \)
   (e) \( n \rightarrow p + e^- + \bar{\nu}_e \)  (f) \( \pi^+ \rightarrow \mu^+ + n \)

16. Occasionally, high-energy muons collide with electrons and produce two neutrinos according to the reaction \( \mu^- + e^- \rightarrow 2\nu \). What kind of neutrinos are they?

17. A K^0_S particle at rest decays into a \( \pi^+ \) and a \( \pi^- \). The mass of the K^0_S is 497.7 MeV/c^2, and the mass of each \( \pi \) meson is 139.6 MeV/c^2. What is the speed of each pion?

18. (a) Show that the proton-decay \( p \rightarrow e^+ + \gamma \) cannot occur because it violates the conservation of baryon number. (b) What If? Imagine that this reaction does occur and the proton is initially at rest. Determine the energies and magnitudes of the momentum of the positron and photon after the reaction. (c) Determine the speed of the positron after the reaction.

19. A \( \Lambda^0 \) particle at rest decays into a proton and a \( \pi^- \) meson. (a) Use the data in Table 46.2 to find the \( Q \) value for this decay in MeV. (b) What is the total kinetic energy shared by the proton and the \( \pi^- \) meson after the decay? (c) What is the total momentum shared by the proton and the \( \pi^- \) meson? (d) The proton and the \( \pi^- \) meson have momenta with the same magnitude after the decay. Do they have equal kinetic energies? Explain.

Section 46.6 Strange Particles and Strangeness

20. The neutral meson \( \rho^0 \) decays by the strong interaction into two pions:
    \[ \rho^0 \rightarrow \pi^+ + \pi^- \quad (T_{1/2} \sim 10^{-25} \text{ s}) \]

The neutral kaon also decays into two pions:
    \[ K^0_S \rightarrow \pi^+ + \pi^- \quad (T_{1/2} \sim 10^{-10} \text{ s}) \]

How do you explain the difference in half-lives?

21. Which of the following processes are allowed by the strong interaction, the electromagnetic interaction, the weak interaction, or no interaction at all?
   (a) \( \pi^- + p \rightarrow 2\eta \)  (b) \( K^- + n \rightarrow \Lambda^0 + \pi^- \)
   (c) \( K^- \rightarrow \pi^- + \pi^0 \)  (d) \( \Omega^- \rightarrow \Xi^- + \pi^0 \)
   (e) \( \eta \rightarrow 2\gamma \)

22. For each of the following forbidden decays, determine what conservation laws are violated.
   (a) \( \mu^- \rightarrow e^- + \gamma \)  (b) \( n \rightarrow p + e^- + \nu_e \)
   (c) \( \Lambda^0 \rightarrow p + \pi^0 \)  (d) \( p \rightarrow e^+ + \pi^0 \)
   (e) \( \Xi^0 \rightarrow n + \pi^0 \)

23. Fill in the missing particle. Assume reaction (a) occurs via the strong interaction and reactions (b) and (c) involve the weak interaction. Assume also the total strangeness changes by one unit if strangeness is not conserved.
   (a) \( K^+ + p \rightarrow ? + p \)  (b) \( \Omega^- \rightarrow ? + \pi^- \)
   (c) \( K^+ \rightarrow ? + \mu^+ + \nu_\mu \)
24. Identify the conserved quantities in the following processes.
   (a) $\Xi^- \rightarrow \Lambda^0 + \mu^- + \nu_\mu$
   (b) $K^0_S \rightarrow 2\pi^0$
   (c) $K^- + p \rightarrow \Sigma^0 + n$
   (d) $\Sigma^0 \rightarrow \Lambda^0 + \gamma$
   (e) $e^+ + e^- \rightarrow \mu^+ + \mu^-$
   (f) $\bar{p} + n \rightarrow \Lambda^0 + \Sigma^-$
   (g) Which reactions cannot occur? Why not?

25. Determine whether or not strangeness is conserved in the following decays and reactions.
   (a) $\Lambda^0 \rightarrow p + \pi^-$
   (b) $\pi^- + p \rightarrow \Lambda^0 + K^0$
   (c) $\bar{p} + p \rightarrow \Lambda^0 + \Lambda^0$
   (d) $\pi^- + p \rightarrow \pi^- + \Sigma^+$
   (e) $\Xi^- \rightarrow \Lambda^0 + \pi^-$
   (f) $\Xi^0 \rightarrow p + \pi^-$

26. The particle decay $\Sigma^+ \rightarrow \pi^+ + n$ is observed in a bubble chamber. Figure P46.26 represents the curved tracks of the particles $\Sigma^+$ and $\pi^+$ and the invisible track of the neutron in the presence of a uniform magnetic field of 1.15 T directed out of the page. The measured radii of curvature are 1.99 m for the $\Sigma^+$ particle and 0.580 m for the $\pi^+$ particle. From this information, we wish to determine the mass of the $\Sigma^+$ particle.
   (a) Find the magnitudes of the momenta of the $\Sigma^+$ and the $\pi^+$ particles in units of MeV/c.
   (b) The angle between the momenta of the $\Sigma^+$ and the $\pi^+$ particles at the moment of decay is $\theta = 64.5^\circ$. Find the magnitude of the momentum of the neutron.
   (c) Calculate the total energy of the $\pi^+$ particle and of the neutron from their known masses ($m_\pi = 139.6$ MeV/c$^2$, $m_n = 939.6$ MeV/c$^2$) and the relativistic energy–momentum relation.
   (d) What is the total energy of the $\Sigma^+$ particle?
   (e) Calculate the mass of the $\Sigma^+$ particle.
   (f) Compare the mass with the value in Table 46.2.

27. If a $K^0_S$ meson at rest decays in $0.900 \times 10^{-10}$ s, how far does a $K^0_S$ meson travel if it is moving at 0.960c?

28. The quark compositions of the $K^0$ and $\Lambda^0$ particles are $d\bar{u}s$ and $u\bar{d}s$, respectively. Show that the charge, baryon number, and strangeness of these particles equal the sums of these numbers for the quark constituents.

29. The reaction $\pi^- + p \rightarrow K^0 + A^0$ occurs with high probability, whereas the reaction $\pi^- + p \rightarrow K^0 + n$ never occurs. Analyze these reactions at the quark level. Show that the first reaction conserves the total number of each type of quark and the second reaction does not.

30. Identify the particles corresponding to the quark states (a) $uu$, (b) $\bar{u}d$, (c) $\bar{s}d$, and (d) $ss$.

31. The quark composition of the proton is $uud$, whereas that of the neutron is $udd$. Show that the charge, baryon number, and strangeness of these particles equal the sums of these numbers for their quark constituents.

32. Analyze each of the following reactions in terms of constituent quarks and show that each type of quark is conserved. (a) $\pi^- + p \rightarrow K^- + \Sigma^+$ (b) $K^- + p \rightarrow K^+ + K^0 + \Omega^-$ (c) Determine the quarks in the final particle for this reaction: $p + p \rightarrow K^0 + \pi^- + \pi^-$ (d) In the reaction in part (c), identify the mystery particle.

33. What is the electrical charge of the baryons with the quark compositions (a) $\bar{u}\bar{u}d$ and (b) $\bar{u}d\bar{d}$? (c) What are these baryons called?

34. Find the number of electrons, and of each species of quark, in 1 L of water.

35. A $\Sigma^+$ particle traveling through matter strikes a proton; then a $\Sigma^-$ and a gamma ray as well as a third particle emerge. Use the quark model of each to determine the identity of the third particle.

36. What If? Imagine that binding energies could be ignored. Find the masses of the $u$ and $d$ quarks from the masses of the proton and neutron.

### Section 46.11 The Cosmic Connection

37. Review. Refer to Section 39.4. Prove that the Doppler shift in wavelength of electromagnetic waves is described by

$$\lambda' = \lambda \sqrt{\frac{1 + v/c}{1 - v/c}}$$

where $\lambda'$ is the wavelength measured by an observer moving at speed $v$ away from a source radiating waves of wavelength $\lambda$.

38. Gravitation and other forces prevent Hubble’s-law expansion from taking place except in systems larger than clusters of galaxies. What If? Imagine that these forces could be ignored and all distances expanded at a rate described by the Hubble constant of $22 \times 10^{-3}$ m/(s·ly). (a) At what rate would the 1.85-m height of a basketball player be increasing? (b) At what rate would the distance between the Earth and the Moon be increasing?

39. Review. The cosmic background radiation is blackbody radiation from a source at a temperature of 2.73 K.
40. Assume dark matter exists throughout space with a uniform density of $6.00 \times 10^{-28}$ kg/m$^3$. (a) Find the amount of such dark matter inside a sphere centered on the Sun, having the Earth’s orbit as its equator. (b) Explain whether the gravitational field of this dark matter would have a measurable effect on the Earth’s revolution.

41. The early Universe was dense with gamma-ray photons of energy $\sim k_BT$ and at such a high temperature that protons and antiprotons were created by the process $\gamma \rightarrow p + \bar{p}$ as rapidly as they annihilated each other. As the Universe cooled in adiabatic expansion, its temperature fell below a certain value and proton pair production became rare. At that time, slightly more protons than antiprotons existed, and essentially all the protons in the Universe today date from that time. (a) Estimate the order of magnitude of the temperature of the Universe when protons condensed out. (b) Estimate the order of magnitude of the temperature of the Universe when electrons condensed out.

42. If the average density of the Universe is small compared with the critical density, the expansion of the Universe described by Hubble’s law proceeds with speeds that are nearly constant over time. (a) Prove that in this case the age of the Universe is given by the inverse of the Hubble constant. (b) Calculate $1/H$ and express it in years.

43. Review. A star moving away from the Earth at 0.280 $c$ emits radiation that we measure to be most intense at the wavelength 500 nm. Determine the surface temperature of this star.

44. Review. Use Stefan’s law to find the intensity of the cosmic background radiation emitted by the fireball of the Big Bang at a temperature of 2.73 K.

45. The first quasar to be identified and the brightest found to date, 3C 273 in the constellation Virgo, was observed to be moving away from the Earth at such high speed that the observed blue 434-nm H$\alpha$ line of hydrogen is Doppler-shifted to 510 nm, in the green portion of the spectrum. (a) How fast is the quasar receding? (b) Edwin Hubble discovered that all objects outside the local group of galaxies are moving away from us, with speeds $v$ proportional to their distances $R$. Hubble’s law is expressed as $v = HR$, where the Hubble constant has the approximate value $H = 22 \times 10^{-3}$ m/(s $\cdot$ ly). Determine the distance from the Earth to this quasar.

46. The various spectral lines observed in the light from a distant quasar have longer wavelengths $\lambda'_n$ than the wavelengths $\lambda_n$ measured in light from a stationary source. Here $n$ is an index taking different values for different spectral lines. The fractional change in wavelength toward the red is the same for all spectral lines. That is, the Doppler redshift parameter $Z$ defined by

$$Z = \frac{\lambda'_n - \lambda_n}{\lambda_n}$$

is common to all spectral lines for one object. In terms of $Z$, use Hubble’s law to determine (a) the speed of recession of the quasar and (b) the distance from the Earth to this quasar.

47. Using Hubble’s law, find the wavelength of the 590-nm sodium line emitted from galaxies (a) $2.00 \times 10^6$ ly, (b) $2.00 \times 10^8$ ly, and (c) $2.00 \times 10^9$ ly away from the Earth.

48. The visible section of the Universe is a sphere centered on the bridge of your nose, with radius 13.7 billion light-years. (a) Explain why the visible Universe is getting larger, with its radius increasing by one light-year in every year. (b) Find the rate at which the volume of the visible section of the Universe is increasing.

49. In Section 13.6, we discussed dark matter along with one proposal for the origin of dark matter: WIMPs, or weakly interacting massive particles. Another proposal is that dark matter consists of large planet-sized objects, called MACHOs, or massive astrophysical compact halo objects, that drift through interstellar space and are not bound to a solar system. Whether WIMPs or MACHOs, suppose astronomers perform theoretical calculations and determine the average density of the observable Universe to be $1.20 \rho_c$. If this value were correct, how many times larger will the Universe become before it begins to collapse? That is, by what factor will the distance between remote galaxies increase in the future?

Section 46.12 Problems and Perspectives

50. Classical general relativity views the structure of space–time as deterministic and well defined down to arbitrarily small distances. On the other hand, quantum general relativity forbids distances smaller than the Planck length given by $L = (\hbar G/c^3)^{1/2}$. (a) Calculate the value of the Planck length. The quantum limitation suggests that after the Big Bang, when all the presently observable section of the Universe was contained within a point-like singularity, nothing could be observed until that singularity grew larger than the Planck length. Because the size of the singularity grew at the speed of light, we can infer that no observations were possible during the time interval required for light to travel the Planck length. (b) Calculate this time interval, known as the Planck time $T$, and state how it compares with the ultrahot epoch mentioned in the text.

Additional Problems

51. For each of the following decays or reactions, name at least one conservation law that prevents it from occurring.

(a) $\pi^- + p \rightarrow \Sigma^+ + \pi^0$

(b) $\mu^- \rightarrow \pi^- + \nu_e$

(c) $p \rightarrow \pi^+ + \pi^+ + \pi^-$
52. Identify the unknown particle on the left side of the following reaction:

53. Assume that the half-life of free neutrons is 614 s. What fraction of a group of free thermal neutrons with kinetic energy 0.040 eV will decay before traveling a distance of 10.0 km?

54. Why is the following situation impossible? A gamma-ray photon with energy 1.05 MeV strikes a stationary electron, causing the following reaction to occur:

Assume all three final particles move with the same speed in the same direction after the reaction.

55. Review. Supernova Shelton 1987A, located approximately 170 000 ly from the Earth, is estimated to have emitted a burst of neutrinos carrying energy (Fig. P46.55). Suppose the average neutrino energy was 6 MeV and your mother’s body presented cross-sectional area 5 000 cm². To an order of magnitude, how many of these neutrinos passed through her?

56. An unstable particle, initially at rest, decays into a positively charged particle of charge $q_1$ and rest energy $E_1$ and a negatively charged particle of charge $-q_2$ and rest energy $E_2$. A uniform magnetic field of magnitude $B$ exists perpendicular to the velocities of the created particles. The radius of curvature of each track is found to be $r$. What is the mass of the original unstable particle?

57. Hubble’s law can be stated in vector form as

Outside the local group of galaxies, all objects are moving away from us with velocities proportional to their positions relative to us. In this form, it sounds as if our location in the Universe is specially privileged. Prove that Hubble’s law is equally true for an observer elsewhere in the Universe. Proceed as follows. Assume we are at the origin of coordinates, one galaxy cluster is at location $r_1$ and has velocity $v_1$ relative to us, and another galaxy cluster has position vector and velocity $r_2$ and $v_2$. Suppose the speeds are nonrelativistic. Consider the frame of reference of an observer in the first of these galaxy clusters. (a) Show that our velocity relative to her, together with the position vector of our galaxy cluster from hers, satisfies Hubble’s law. (b) Show that the position and velocity of cluster 2 relative to cluster 1 satisfy Hubble’s law.

58. A meson at rest decays according to $\pi^+ \rightarrow \mu^+ \nu$. Assume the antineutrino has no mass and moves off with the speed of light. Take $139.6$ MeV and $105.7$ MeV. What is the energy carried off by the neutrino?

59. An unstable particle, initially at rest, decays into a proton (rest energy 938.3 MeV) and a negative pion (rest energy 139.6 MeV). A uniform magnetic field of 0.250 T exists perpendicular to the velocities of the created particles. The radius of curvature of each track is found to be 1.33 m. What is the mass of the original unstable particle?

60. An unstable particle, initially at rest, decays into a positively charged particle of charge $q$ and rest energy $E$ and a negatively charged particle of charge $-q$ and rest energy $E$. A uniform magnetic field of magnitude $B$ exists perpendicular to the velocities of the created particles. The radius of curvature of each track is found to be $r$. What is the mass of the original unstable particle?

61. (a) What processes are described by the Feynman diagrams in Figure P46.61? (b) What is the exchanged particle in each process?

The energy flux carried by neutrinos from the Sun is estimated to be on the order of 0.400 W/m² at the Earth’s surface. Estimate the fractional mass loss of the Sun over 10 yr due to the emission of neutrinos. The mass of the Sun is 1.989 kg. The Earth–Sun distance is equal to 1.496 AU.
62. Identify the mediators for the two interactions described in the Feynman diagrams shown in Figure P46.62.

![Feynman Diagram](image)

**Figure P46.62**

63. **Review.** The energy required to excite an atom is on the order of 1 eV. As the temperature of the Universe dropped below a threshold, neutral atoms could form from plasma and the Universe became transparent. Use the Boltzmann distribution function $e^{-E/k_B T}$ to find the order of magnitude of the threshold temperature at which 1.00% of a population of photons has energy greater than 1.00 eV.

64. A $\Sigma^0$ particle at rest decays according to $\Sigma^0 \rightarrow \Lambda^0 + \gamma$. Find the gamma-ray energy.

65. Two protons approach each other head-on, each with 70.4 MeV of kinetic energy, and engage in a reaction in which a proton and positive pion emerge at rest. What third particle, obviously uncharged and therefore difficult to detect, must have been created?

66. Two protons approach each other with velocities of equal magnitude in opposite directions. What is the minimum kinetic energy of each proton if the two are to produce a $\pi^+$ meson at rest in the reaction $p + p \rightarrow p + n + \pi^+$?

**Challenge Problems**

67. Determine the kinetic energies of the proton and pion resulting from the decay of a $\Lambda^0$ at rest:

$\Lambda^0 \rightarrow p + \pi^-$

68. A particle of mass $m_1$ is fired at a stationary particle of mass $m_2$, and a reaction takes place in which new particles are created out of the incident kinetic energy. Taken together, the product particles have total mass $m_3$. The minimum kinetic energy the bombarding particle must have so as to induce the reaction is called the threshold energy. At this energy, the kinetic energy of the products is a minimum, so the fraction of the incident kinetic energy that is available to create new particles is a maximum. This condition is met when all the product particles have the same velocity and the particles have no kinetic energy of motion relative to one another. (a) By using conservation of relativistic energy and momentum and the relativistic energy–momentum relation, show that the threshold kinetic energy is

$$K_{\text{min}} = \frac{\left[ m_2^2 - (m_1 + m_2)^2 \right]c^2}{2m_2}$$

Calculate the threshold kinetic energy for each of the following reactions: (b) $p + p \rightarrow p + p + p + \bar{p}$ (one of the initial protons is at rest, and antiprotons are produced); (c) $\pi^- + p \rightarrow K^0 + \Lambda^0$ (the proton is at rest, and strange particles are produced); (d) $p + p \rightarrow p + p + \pi^0$ (one of the initial protons is at rest, and pions are produced); and (e) $p + \bar{p} \rightarrow Z^0$ (one of the initial particles is at rest, and $Z^0$ particles of mass 91.2 GeV/c$^2$ are produced).

69. A free neutron beta decays by creating a proton, an electron, and an antineutrino according to the reaction $n \rightarrow p + e^- + \bar{\nu}$. **What If?** Imagine that a free neutron were to decay by creating a proton and electron according to the reaction $n \rightarrow p + e^-$ and assume the neutron is initially at rest in the laboratory.

(a) Determine the energy released in this reaction.
(b) Energy and momentum are conserved in the reaction. Determine the speeds of the proton and the electron after the reaction. (c) Is either of these particles moving at a relativistic speed? Explain.

70. The cosmic rays of highest energy are mostly protons, accelerated by unknown sources. Their spectrum shows a cutoff at an energy on the order of $10^{20}$ eV. Above that energy, a proton interacts with a photon of cosmic microwave background radiation to produce mesons, for example, according to $p + \gamma \rightarrow p + \pi^0$. Demonstrate this fact by taking the following steps.

(a) Find the minimum photon energy required to produce this reaction in the reference frame where the total momentum of the photon–proton system is zero.

(b) The reaction was observed experimentally in the 1950s with photons of a few hundred MeV. Use Wien’s displacement law to find the wavelength of a photon at the peak of the blackbody spectrum of the primordial microwave background radiation, with a temperature of 2.73 K.

(c) Find the energy of this photon.

(d) Consider the reaction in part (a) in a moving reference frame so that the photon is the same as that in part (c). Calculate the energy of the proton in this frame, which represents the Earth reference frame.

71. Assume the average density of the Universe is equal to the critical density. (a) Prove that the age of the Universe is given by $2/(3H)$. (b) Calculate $2/(3H)$ and express it in years.

72. The most recent naked-eye supernova was Supernova Shelton 1987A (Fig. P46.55). It was 170,000 ly away in the Large Magellanic Cloud, a satellite galaxy of the Milky Way. Approximately 3 h before its optical brightening was noticed, two neutrino detection experiments simultaneously registered the first neutrinos from an identified source other than the Sun. The Irvine–Michigan–Brookhaven experiment in a salt mine in Ohio registered eight neutrinos over a 6-s period, and the Kamiokande II experiment in a zinc mine in Japan counted eleven neutrinos in 13 s. (Because the supernova is far south in the sky, these neutrinos entered the detectors from below. They passed through the Earth before they were by chance absorbed by nuclei in the detectors.) The neutrino energies were between approximately 8 MeV and
40 MeV. If neutrinos have no mass, neutrinos of all energies should travel together at the speed of light, and the data are consistent with this possibility. The arrival times could vary simply because neutrinos were created at different moments as the core of the star collapsed into a neutron star. If neutrinos have nonzero mass, lower-energy neutrinos should move comparatively slowly. The data are consistent with a 10-MeV neutrino requiring at most approximately 10 s more than a photon would require to travel from the supernova to us. Find the upper limit that this observation sets on the mass of a neutrino. (Other evidence sets an even tighter limit.)

73. A rocket engine for space travel using photon drive and matter–antimatter annihilation has been suggested. Suppose the fuel for a short-duration burn consists of \( N \) protons and \( N \) antiprotons, each with mass \( m \).

(a) Assume all the fuel is annihilated to produce photons. When the photons are ejected from the rocket, what momentum can be imparted to it?

(b) **What If?** If half the protons and antiprotons annihilate each other and the energy released is used to eject the remaining particles, what momentum could be given to the rocket?

(c) Which scheme results in the greater change in speed for the rocket?

\(^a\) The base SI units are given in uppercase letters.
\(^b\) The symbols M, L, T, K, and Q denote mass, length, time, temperature, and charge, respectively.
This appendix in mathematics is intended as a brief review of operations and methods. Early in this course, you should be totally familiar with basic algebraic techniques, analytic geometry, and trigonometry. The sections on differential and integral calculus are more detailed and are intended for students who have difficulty applying calculus concepts to physical situations.

B.1 Scientific Notation

Many quantities used by scientists often have very large or very small values. The speed of light, for example, is about 300 000 000 m/s, and the ink required to make the dot over an i in this textbook has a mass of about 0.000 000 001 kg. Obviously, it is very cumbersome to read, write, and keep track of such numbers. We avoid this problem by using a method incorporating powers of the number 10:

\[ 10^0 = 1 \]
\[ 10^1 = 10 \]
\[ 10^2 = 10 \times 10 = 100 \]
\[ 10^3 = 10 \times 10 \times 10 = 1,000 \]
\[ 10^4 = 10 \times 10 \times 10 \times 10 = 10,000 \]
\[ 10^5 = 10 \times 10 \times 10 \times 10 \times 10 = 100,000 \]

and so on. The number of zeros corresponds to the power to which ten is raised, called the exponent of ten. For example, the speed of light, 300 000 000 m/s, can be expressed as 3.00 × 10^8 m/s.

In this method, some representative numbers smaller than unity are the following:

\[ 10^{-1} = \frac{1}{10} = 0.1 \]
\[ 10^{-2} = \frac{1}{10 \times 10} = 0.01 \]
\[ 10^{-3} = \frac{1}{10 \times 10 \times 10} = 0.001 \]
\[ 10^{-4} = \frac{1}{10 \times 10 \times 10 \times 10} = 0.0001 \]
\[ 10^{-5} = \frac{1}{10 \times 10 \times 10 \times 10 \times 10} = 0.00001 \]

In these cases, the number of places the decimal point is to the left of the digit 1 equals the value of the (negative) exponent. Numbers expressed as some power of ten multiplied by another number between one and ten are said to be in scientific notation. For example, the scientific notation for 5 943 000 000 is 5.943 × 10^9 and that for 0.000 083 2 is 8.32 × 10^{-5}. 
When numbers expressed in scientific notation are being multiplied, the following general rule is very useful:

\[10^n \times 10^m = 10^{n+m}\]  \hfill (B.1)

where \(n\) and \(m\) can be any numbers (not necessarily integers). For example, \(10^2 \times 10^7 = 10^9\). The rule also applies if one of the exponents is negative: \(10^3 \times 10^{-5} = 10^{-2}\).

When dividing numbers expressed in scientific notation, note that

\[\frac{10^n}{10^m} = 10^{n-m} = 10^{n-w}\]  \hfill (B.2)

Exercises

With help from the preceding rules, verify the answers to the following equations:

1. \(8.6 \times 10^4\)  
2. \(9.816 \times 10^6\)  
3. \(3.98 \times 10^{-2}\)  
4. \((4.0 \times 10^3)(9.0 \times 10^9) = 3.6 \times 10^{18}\)  
5. \((3.0 \times 10^{-7})(6.0 \times 10^{-12}) = 1.8 \times 10^{-4}\)  
6. \(\frac{75 \times 10^{-11}}{5.0 \times 10^{-3}} = 1.5 \times 10^{-7}\)  
7. \(\frac{(3 \times 10^6)(8 \times 10^{-2})}{(2 \times 10^5)(6 \times 10^3)} = 2 \times 10^{-18}\)

**B.2 Algebra**

**Some Basic Rules**

When algebraic operations are performed, the laws of arithmetic apply. Symbols such as \(x\), \(y\), and \(z\) are usually used to represent unspecified quantities, called the **unknowns**.

First, consider the equation

\[8x = 32\]

If we wish to solve for \(x\), we can divide (or multiply) each side of the equation by the same factor without destroying the equality. In this case, if we divide both sides by 8, we have

\[\frac{8x}{8} = \frac{32}{8}\]

\[x = 4\]

Next consider the equation

\[x + 2 = 8\]

In this type of expression, we can add or subtract the same quantity from each side. If we subtract 2 from each side, we have

\[x + 2 - 2 = 8 - 2\]

\[x = 6\]

In general, if \(x + a = b\), then \(x = b - a\).

Now consider the equation

\[\frac{x}{5} = 9\]
Appendix B  Mathematics Review

If we multiply each side by 5, we are left with \( x \) on the left by itself and 45 on the right:

\[
\left( \frac{x}{5} \right)(5) = 9 \times 5
\]

\[
x = 45
\]

In all cases, whatever operation is performed on the left side of the equality must also be performed on the right side.

The following rules for multiplying, dividing, adding, and subtracting fractions should be recalled, where \( a, b, c, \) and \( d \) are four numbers:

<table>
<thead>
<tr>
<th>Rule</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Multiplying</td>
<td>( \left( \frac{a}{b} \right) \left( \frac{c}{d} \right) = \frac{ac}{bd} )</td>
</tr>
<tr>
<td></td>
<td>( \frac{2}{3} \left( \frac{4}{5} \right) = \frac{8}{15} )</td>
</tr>
<tr>
<td>Dividing</td>
<td>( \frac{a}{b} \div \frac{c}{d} = \frac{ad}{bc} )</td>
</tr>
<tr>
<td></td>
<td>( \frac{2/3}{4/5} = \frac{(2)(5)}{(4)(3)} = \frac{10}{12} )</td>
</tr>
<tr>
<td>Adding</td>
<td>( \frac{a}{b} \pm \frac{c}{d} = \frac{ad \pm bc}{bd} )</td>
</tr>
<tr>
<td></td>
<td>( \frac{2}{3} - \frac{4}{5} = \frac{(2)(5) - (4)(3)}{(3)(5)} = \frac{2}{15} )</td>
</tr>
</tbody>
</table>

**Exercises**

In the following exercises, solve for \( x \).

<table>
<thead>
<tr>
<th>Answers</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1. ( a = \frac{1}{1+x} ) ( x = \frac{1-a}{a} )</td>
<td></td>
</tr>
<tr>
<td>2. ( 3x - 5 = 13 ) ( x = 6 )</td>
<td></td>
</tr>
<tr>
<td>3. ( ax - 5 = bx + 2 ) ( x = \frac{7}{a-b} )</td>
<td></td>
</tr>
<tr>
<td>4. ( \frac{5}{2x + 6} = \frac{3}{4x + 8} ) ( x = -\frac{11}{7} )</td>
<td></td>
</tr>
</tbody>
</table>

**Powers**

When powers of a given quantity \( x \) are multiplied, the following rule applies:

\[ x^a x^m = x^{a+m} \]  \((B.3)\)

For example, \( x^2 x^4 = x^{2+4} = x^6 \).

When dividing the powers of a given quantity, the rule is

\[ \frac{x^a}{x^m} = x^{a-m} \] \((B.4)\)

For example, \( x^6/x^2 = x^{6-2} = x^4 \).

A power that is a fraction, such as \( \frac{1}{2} \), corresponds to a root as follows:

\[ x^{1/2} = \sqrt{x} \] \((B.5)\)

For example, \( 4^{1/3} = \sqrt[3]{4} = 1.5874 \). (A scientific calculator is useful for such calculations.)

Finally, any quantity \( x^a \) raised to the \( m \)th power is

\[ (x^a)^m = x^{am} \] \((B.6)\)

<table>
<thead>
<tr>
<th>Table B.1 Rules of Exponents</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x^0 = 1 )</td>
</tr>
<tr>
<td>( x^1 = x )</td>
</tr>
<tr>
<td>( x^a x^m = x^{a+m} )</td>
</tr>
<tr>
<td>( x^a / x^m = x^{a-m} )</td>
</tr>
<tr>
<td>( x^{1/n} = \sqrt[n]{x} )</td>
</tr>
<tr>
<td>( (x^a)^n = x^{an} )</td>
</tr>
</tbody>
</table>

Table B.1 summarizes the rules of exponents.

**Exercises**

Verify the following equations:

1. \( 3^2 \times 3^3 = 243 \)
2. \( x^5 x^{-8} = x^{-3} \)
3. \( x^{10}/x^{-5} = x^{15} \)
4. \( 5^{1/3} = 1.709976 \) (Use your calculator.)
5. \( 60^{1/4} = 2.783158 \) (Use your calculator.)
6. \( (x^3)^3 = x^{12} \)

**Factoring**

Some useful formulas for factoring an equation are the following:

- \( ax + ay + az = a(x + y + z) \)  
  common factor
- \( a^2 + 2ab + b^2 = (a + b)^2 \)  
  perfect square
- \( a^2 - b^2 = (a + b)(a - b) \)  
  differences of squares

**Quadratic Equations**

The general form of a quadratic equation is

\[
ax^2 + bx + c = 0  \tag{B.7}
\]

where \( x \) is the unknown quantity and \( a, b, \) and \( c \) are numerical factors referred to as *coefficients* of the equation. This equation has two roots, given by

\[
x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}  \tag{B.8}
\]

If \( b^2 \geq 4ac \), the roots are real.

**Example B.1**

The equation \( x^2 + 5x + 4 = 0 \) has the following roots corresponding to the two signs of the square-root term:

\[
x = \frac{-5 \pm \sqrt{5^2 - 4(1)(4)}}{2(1)} = \frac{-5 \pm \sqrt{9}}{2} = \frac{-5 \pm 3}{2}
\]

\[
x_+ = \frac{-5 + 3}{2} = -1 \quad x_- = \frac{-5 - 3}{2} = -4
\]

where \( x_+ \) refers to the root corresponding to the positive sign and \( x_- \) refers to the root corresponding to the negative sign.

**Exercises**

Solve the following quadratic equations:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>( x^2 + 2x - 3 = 0 )</td>
</tr>
<tr>
<td>2.</td>
<td>( 2x^2 - 5x + 2 = 0 )</td>
</tr>
<tr>
<td>3.</td>
<td>( 2x^2 - 4x - 9 = 0 )</td>
</tr>
</tbody>
</table>

**Linear Equations**

A linear equation has the general form

\[
y = mx + b  \tag{B.9}
\]
Example B.2

Solve the two simultaneous equations

(1) \[ 5x + 2y = -8 \]
(2) \[ 4x - y = 4 \]

Solution

From Equation (2), 2. Substitution of this equation into Equation (1) gives

\[ 5x + 2(4) = -8 \]
\[ 5x + 8 = -8 \]
\[ 5x = -16 \]
\[ x = -3.2 \]

Note that and can have either positive or negative values. If 0, the straight line has a positive slope as in Figure B.1. If 0, the straight line has a negative slope. In Figure B.1, both and are positive. Three other possible situations are shown in Figure B.2.

Exercises

Draw graphs of the following straight lines:
(a) 3
(b) \[ x = 2 \]
(c) \[ y = 3 \]

2. Find the slopes of the straight lines described in Exercise 1.

Answers
(a) 5  (b) 2  (c)

3. Find the slopes of the straight lines that pass through the following sets of points:
(a) (0, 4) and (4, 2)  (b) (0, 0) and (2, 5)  (c) (5, 2) and (4, 5)

Answers
(a) (b) (c)

Solving Simultaneous Linear Equations

Consider the equation 3 \[ 5x + 2y = -8 \], which has two unknowns, and . Such an equation does not have a unique solution. For example, \( x = 0, y = 3 \), \( x = 5, y = 0 \), and \( x = 2, y = -8 \) are all solutions to this equation.

If a problem has two unknowns, a unique solution is possible only if we have two pieces of information. In most common cases, those two pieces of information are equations. In general, if a problem has unknowns, its solution requires equations.

To solve two simultaneous equations involving two unknowns, and , we solve one of the equations for in terms of , substitute this expression into the other equation.

In some cases, the two pieces of information may be (1) one equation and (2) a condition on the solutions. For example, suppose we have the equation and the condition that and must be the smallest positive nonzero integers possible.

Then, the single equation does not allow a unique solution, but the addition of the condition gives us that and...
Alternative Solution Multiply each term in Equation (1) by the factor 2 and add the result to Equation (2):

\[
\begin{array}{c}
10 &= -16 \\
4 &= 4 \\
12 &= -12 \\
1 &= 1
\end{array}
\]

Two linear equations containing two unknowns can also be solved by a graphical method. If the straight lines corresponding to the two equations are plotted in a conventional coordinate system, the intersection of the two lines represents the solution. For example, consider the two equations

\[
2 = -1
\]

These equations are plotted in Figure B.3. The intersection of the two lines has the coordinates \(x = 5\) and \(y = 3\), which represents the solution to the equations. You should check this solution by the analytical technique discussed earlier.

Exercises
Solve the following pairs of simultaneous equations involving two unknowns:

Answers

1. 5, 2.

2. 65, 3.27

3. 2

Logarithms
Suppose a quantity is expressed as a power of some quantity

(B.11)

The number is called the base number. The logarithm of with respect to the base is equal to the exponent to which the base must be raised to satisfy the expression

(B.12)

Conversely, the antilogarithm of is the number

(B.13)

In practice, the two bases most often used are base 10, called the common logarithm base, and base \(e = 2.718\), called Euler’s constant or the natural logarithm base. When common logarithms are used,

(B.14)
When natural logarithms are used,

\[ \ln \quad \text{or} \quad \log \]

For example, \( \log_{10} 5 = 0.709 \), so antilog \( 0.709 \) = 5. Likewise, \( \ln 52 \) = 3.951, so antiln 3.951 = 52.

In general, note you can convert between base 10 and base \( e \) with the equality

\[ \ln \quad 2.302585 \quad \log_{10} \]

Finally, some useful properties of logarithms are the following:

\[
\begin{align*}
\log{ab} &= \log{a} + \log{b} \\
\log{\frac{a}{b}} &= \log{a} - \log{b} \\
\log{a^b} &= b \log{a} \\
\ln{a^b} &= b \ln{a} \\
\ln{e} &= 1 \\
\ln{1} &= 0 \\
\ln{(\ln{x})} &= \frac{\ln{(\ln{x})}}{\ln{\ln{x}}} \\
\end{align*}
\]

## B.3 Geometry

The **distance** between two points having coordinates \((x_1, y_1)\) and \((x_2, y_2)\) is

\[ \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \quad \text{(B.17)} \]

Two angles are equal if their sides are perpendicular, right side to right side and left side to left side. For example, the two angles marked \( \angle \) in Figure B.4 are the same because of the perpendicularity of the sides of the angles. To distinguish the left and right sides of an angle, imagine standing at the angle’s apex and facing into the angle.

**Radian measure:** The arc length \( s \) of a circular arc (Fig. B.5) is proportional to the radius \( r \) for a fixed value of \( \theta \) (in radians):

\[ s = r \theta \]

Table B.2 gives the **areas** and **volumes** for several geometric shapes used throughout this text.

- The equation of a **straight line** (Fig. B.6) is
  \[ y = mx + b \]
  \[ \text{(B.19)} \]

  where \( b \) is the \(-\)-intercept and \( m \) is the slope of the line.

- The equation of a **circle** of radius \( r \) centered at the origin is
  \[ x^2 + y^2 = r^2 \]
  \[ \text{(B.20)} \]

- The equation of an **ellipse** having the origin at its center (Fig. B.7) is
  \[ \frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \]
  \[ \text{(B.21)} \]

  where \( a \) is the length of the semimajor axis (the longer one) and \( b \) is the length of the semiminor axis (the shorter one).

- The equation of a **parabola** the vertex of which is at \((h, k)\) (Fig. B.8) is
  \[ y = ax^2 + bx + c \]
  \[ \text{(B.22)} \]
The equation of a **rectangular hyperbola** (Fig. B.9) is

\[ \text{constant} \]  

(B.23)

---

**B.4 Trigonometry**

That portion of mathematics based on the special properties of the right triangle is called trigonometry. By definition, a right triangle is a triangle containing a 90° angle. Consider the right triangle shown in Figure B.10, where side \( a \) is opposite the angle \( \theta \), side \( b \) is adjacent to the angle \( \theta \), and side \( c \) is the hypotenuse of the triangle.

The three basic trigonometric functions defined by such a triangle are the sine (\( \sin \)), cosine (\( \cos \)), and tangent (\( \tan \)). In terms of the angle \( \theta \), these functions are defined as follows:

\[
\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} \tag{B.24}
\]

\[
\cos \theta = \frac{\text{side adjacent to}}{\text{hypotenuse}} \tag{B.25}
\]

\[
\tan \theta = \frac{\text{side opposite}}{\text{side adjacent to}} \tag{B.26}
\]

The Pythagorean theorem provides the following relationship among the sides of a right triangle:

\[
\sin^2 \theta + \cos^2 \theta = 1 \tag{B.27}
\]

From the preceding definitions and the Pythagorean theorem, it follows that

\[
\sin \theta + \cos \theta = 1
\]

\[
\tan \theta = \frac{\sin \theta}{\cos \theta}
\]

The cosecant, secant, and cotangent functions are defined by

\[
\csc \theta = \frac{1}{\sin \theta}, \quad \sec \theta = \frac{1}{\cos \theta}, \quad \cot \theta = \frac{1}{\tan \theta}
\]
Some properties of trigonometric functions are the following:

\[
\sin \theta = \cos \left(90^\circ - \theta\right) \\
\cos \theta = \sin \left(90^\circ - \theta\right) \\
\cot \theta = \tan \left(90^\circ - \theta\right)
\]

The following relationships apply to any triangle as shown in Figure B.11:

\[
\alpha + \beta + \gamma = 180
\]

Law of cosines

\[
bc \cos \alpha + ac \cos \beta + ab \cos \gamma = 0
\]

Law of sines

\[
\frac{\sin \alpha}{a} = \frac{\sin \beta}{b} = \frac{\sin \gamma}{c}
\]

Table B.3 lists a number of useful trigonometric identities.

Example B.3

Consider the right triangle in Figure B.12 in which \( a = 2.00 \), \( b = 5.00 \), and \( c \) is unknown. From the Pythagorean theorem, we have

\[
2.00^2 + 5.00^2 = c^2 \\
c = \sqrt{2.00^2 + 5.00^2} = 5.39
\]

To find the angle \( \theta \), note that

\[
\tan \theta = -\frac{2.00}{5.00} = 0.400
\]
Exercises

In Figure B.13, identify (a) the side opposite (b) the side adjacent to and then find (c) \( \cos \), (d) \( \sin \), and (e) \( \tan \).

Answers

(a) 3 (b) 3 (c) (d) (e)

2. In a certain right triangle, the two sides that are perpendicular to each other are 5.00 m and 7.00 m long. What is the length of the third side?

Answer

8.60 m

3. A right triangle has a hypotenuse of length 3.0 m, and one of its angles is 30°. (a) What is the length of the side opposite the 30° angle? (b) What is the side adjacent to the 30° angle?

Answers

(a) 1.5 m (b) 2.6 m

Figure B.13 (Exercise 1)

For << 1, the following approximations can be used:

\[ \begin{align*}
\sin x & \approx x \\
\cos x & \approx 1 \\
\tan x & \approx x
\end{align*} \]

B.6 Differential Calculus

In various branches of science, it is sometimes necessary to use the basic tools of calculus, invented by Newton, to describe physical phenomena. The use of calculus is fundamental in the treatment of various problems in Newtonian mechanics, electricity, and magnetism. In this section, we simply state some basic properties and "rules of thumb" that should be a useful review to the student.

The approximations for the functions \( \sin \), \( \cos \), and \( \tan \) are for 0.1 rad.
First, a function must be specified that relates one variable to another (e.g., a coordinate as a function of time). Suppose one of the variables is called (the dependent variable), and the other (the independent variable). We might have a function relationship such as

\[ ax + bx + cx \]

If \( a \) and \( b \) are specified constants, can be calculated for any value of \( x \). We usually deal with continuous functions, that is, those for which \( x \) varies “smoothly” with.

The derivative of \( f \) with respect to \( x \) is defined as the limit as \( \Delta \) approaches zero of the slopes of chords drawn between two points on the \( f \) versus \( x \) curve. Mathematically, we write this definition as

\[
\frac{dy}{dx} = \lim_{\Delta \to 0} \frac{f(x + \Delta) - f(x)}{\Delta}
\]

where \( f(x + \Delta) \) and \( f(x) \) are defined as \( f(x + \Delta) = f(x) + \Delta \) and \( f(x) = f(x) \) (Fig. B.14). Note that \( dx \) does not mean \( f(x) \) divided by \( \Delta \), but rather is simply a notation of the limiting process of the derivative as defined by Equation B.28.

A useful expression to remember when \( \frac{dy}{dx} = n \), where \( n \) is a constant and is any positive or negative number (integer or fraction), is

\[
\frac{dy}{dx} = na \]

If \( f \) is a polynomial or algebraic function of \( x \), we apply Equation B.29 to each term in the polynomial and take \( \frac{\text{constant}}{x} \) = 0. In Examples B.4 through B.7, we evaluate the derivatives of several functions.

### Special Properties of the Derivative

**A. Derivative of the product of two functions** If a function \( f \) is given by the product of two functions—say, \( f(x) \) and \( g(x) \)—the derivative of \( f(x)g(x) \) is defined as

\[
\frac{dy}{dx} = \left( \frac{df}{dx} \right) \left( \frac{dg}{dx} \right)
\]

**B. Derivative of the sum of two functions** If a function \( f(x) \) is equal to the sum of two functions, the derivative of the sum is equal to the sum of the derivatives:

\[
\frac{dy}{dx} = \frac{df}{dx} + \frac{dg}{dx}
\]

**C. Chain rule of differential calculus** If \( y = f(x) \) and \( x = g(y) \), then can be written as the product of two derivatives:

\[
\frac{dy}{dx} = \frac{dy}{dz} \frac{dz}{dx}
\]

**D. The second derivative** The second derivative of \( f(x) \) with respect to \( x \) is defined as the derivative of the function \( \frac{dy}{dx} \) (the derivative of the derivative). It is usually written as

\[
\frac{d^2y}{dx^2} = \frac{d}{dx} \left( \frac{dy}{dx} \right)
\]

Some of the more commonly used derivatives of functions are listed in Table B.4.

Note: The symbols \( a \) and \( n \) represent constants.
Example B.4

Suppose \( y(x) \) (that is, \( y \) as a function of \( x \)) is given by

\[
y(x) = ax^3 + bx + c
\]

where \( a \) and \( b \) are constants. It follows that

\[
y(x + \Delta x) = a(x + \Delta x)^3 + b(x + \Delta x) + c
\]

\[
= a(x^3 + 3x^2 \Delta x + 3x \Delta x^2 + \Delta x^3) + b(x + \Delta x) + c
\]

so

\[
\Delta y = y(x + \Delta x) - y(x) = a(3x^2 \Delta x + 3x \Delta x^2 + \Delta x^3) + b \Delta x
\]

Substituting this into Equation B.28 gives

\[
\frac{dy}{dx} = \lim_{\Delta x \to 0} \frac{\Delta y}{\Delta x} = \lim_{\Delta x \to 0} [3ax^2 + 3ax \Delta x + a \Delta x^2] + b
\]

\[
\frac{dy}{dx} = 3ax^2 + b
\]

Example B.5

Find the derivative of

\[
y(x) = 8x^5 + 4x^3 + 2x + 7
\]

Solution

Applying Equation B.29 to each term independently and remembering that \( d/dx \) (constant) = 0, we have

\[
\frac{dy}{dx} = 8(5)x^4 + 4(3)x^2 + 2(1)x^0 + 0
\]

\[
\frac{dy}{dx} = 40x^4 + 12x^2 + 2
\]

Example B.6

Find the derivative of \( y(x) = x^3/(x + 1)^2 \) with respect to \( x \).

Solution

We can rewrite this function as \( y(x) = x^3(x + 1)^{-2} \) and apply Equation B.30:

\[
\frac{dy}{dx} = (x + 1)^{-2} \frac{d}{dx}(x^3) + x^3 \frac{d}{dx}(x + 1)^{-2}
\]

\[
= (x + 1)^{-2} 3x^2 + x^3 (-2)(x + 1)^{-3}
\]

\[
\frac{dy}{dx} = \frac{3x^2}{(x + 1)^2} - \frac{2x^3}{(x + 1)^3} = \frac{x^3(x + 3)}{(x + 1)^3}
\]
Example B.7

A useful formula that follows from Equation B.30 is the derivative of the quotient of two functions. Show that

\[
\frac{d}{dx} \left( \frac{g(x)}{h(x)} \right) = \frac{\frac{dg}{dx} - \frac{dh}{dx}}{h^2}
\]

Solution

We can write the quotient as \( gh^{-1} \) and then apply Equations B.29 and B.30:

\[
\frac{d}{dx} \left( \frac{g}{h} \right) = \frac{d}{dx} (gh^{-1}) = g \frac{d}{dx} (h^{-1}) + h^{-1} \frac{d}{dx} (g) \\
= -gh^{-2} \frac{dh}{dx} + h^{-1} \frac{dg}{dx} \\
= \frac{\frac{dg}{dx} - \frac{dh}{dx}}{h^2}
\]

B.7 Integral Calculus

We think of integration as the inverse of differentiation. As an example, consider the expression

\[
f(x) = \frac{dy}{dx} = 3ax^2 + b
\]

(B.34)

which was the result of differentiating the function

\( y(x) = ax^3 + bx + c \)

in Example B.4. We can write Equation B.34 as \( dy = f(x) \, dx = (3ax^2 + b) \, dx \) and obtain \( y(x) \) by “summing” over all values of \( x \). Mathematically, we write this inverse operation as

\[
y(x) = \int f(x) \, dx
\]

For the function \( f(x) \) given by Equation B.34, we have

\[
y(x) = \int (3ax^2 + b) \, dx = ax^3 + bx + c
\]

where \( c \) is a constant of the integration. This type of integral is called an indefinite integral because its value depends on the choice of \( c \).

A general indefinite integral \( I(x) \) is defined as

\[
I(x) = \int f(x) \, dx
\]

(B.35)

where \( f(x) \) is called the integrand and \( f(x) = dI(x)/dx \).

For a general continuous function \( f(x) \), the integral can be interpreted geometrically as the area under the curve bounded by \( f(x) \) and the \( x \) axis, between two specified values of \( x \), say, \( x_1 \) and \( x_2 \), as in Figure B.15.

The area of the blue element in Figure B.15 is approximately \( f(x) \Delta x \). If we sum all these area elements between \( x_1 \) and \( x_2 \) and take the limit of this sum as \( \Delta x \to 0 \),
we obtain the \textit{true} area under the curve bounded by \( \) and the \( x \) axis, between the limits \( a \) and \( b \), and

\[
\text{Area} = \lim_{n \to \infty} \frac{b-a}{n} \sum_{i=1}^{n} f(x_i) 
\] (B.36)

Integrals of the type defined by Equation B.36 are called \textbf{definite integrals}. One common integral that arises in practical situations has the form

\[
dx
\] (B.37)

This result is obvious, being that differentiation of the right-hand side with respect to \( x \) gives \( f(x) \) directly. If the limits of the integration are known, this integral becomes a \textit{definite integral} and is written

\[
dx \quad \text{between the limits } a \text{ and } b
\] (B.38)

\section*{Examples}

1. \( dx \)

2. \( dx \)

3. \( dx \)

\section*{Partial Integration}

Sometimes it is useful to apply the method of \textit{partial integration} (also called “integrating by parts”) to evaluate certain integrals. This method uses the property

\[
dv \quad uv \quad du
\] (B.39)

where \( u \) and \( v \) are carefully chosen so as to reduce a complex integral to a simpler one. In many cases, several reductions have to be made. Consider the function

\[
dx
\]

which can be evaluated by integrating by parts twice. First, if we choose \( \) we obtain

\[
dx
\]
Now, in the second term, choose \( u = x, \ v = e^x \), which gives
\[
\int x^2 e^x \, dx = x^2 e^x - 2x e^x + 2 \int e^x \, dx + c_1
\]
or
\[
\int x^2 e^x \, dx = x^2 e^x - 2x e^x + 2 e^x + c_2
\]

The Perfect Differential
Another useful method to remember is that of the perfect differential, in which we look for a change of variable such that the differential of the function is the differential of the independent variable appearing in the integrand. For example, consider the integral
\[
I(x) = \int \cos^2 x \sin x \, dx
\]
This integral becomes easy to evaluate if we rewrite the differential as \( d(\cos x) = -\sin x \, dx \). The integral then becomes
\[
\int \cos^2 x \sin x \, dx = -\int \cos^2 x \, d(\cos x)
\]
If we now change variables, letting \( y = \cos x \), we obtain
\[
\int \cos^2 x \sin x \, dx = -\int y^2 \, dy = -\frac{y^3}{3} + c = -\frac{\cos^3 x}{3} + c
\]

Table B.5 lists some useful indefinite integrals. Table B.6 gives Gauss’s probability integral and other definite integrals. A more complete list can be found in various handbooks, such as The Handbook of Chemistry and Physics (Boca Raton, FL: CRC Press, published annually).

I_{2n+1} &= (-1)^n \frac{d^n}{da^n} I_1
\end{align*}
\]
Appendix B  Mathematics Review

B.8 Propagation of Uncertainty

In laboratory experiments, a common activity is to take measurements that act as raw data. These measurements are of several types—length, time interval, temperature, voltage, and so on—and are taken by a variety of instruments. Regardless of the measurement and the quality of the instrumentation, there is always uncertainty associated with a physical measurement. This uncertainty is a combination of that associated with the instrument and that related to the system being measured. An example of the former is the inability to exactly determine the position of a length measurement between the lines on a meterstick. An example of uncertainty related to the system being measured is the variation of temperature within a sample of water so that a single temperature for the sample is difficult to determine.

Uncertainties can be expressed in two ways. Absolute uncertainty refers to an uncertainty expressed in the same units as the measurement. Therefore, the length of a computer disk label might be expressed as $(5.5 \pm 0.1) \text{ cm}$. The uncertainty of $\pm 0.1 \text{ cm}$ by itself is not descriptive enough for some purposes, however. This uncertainty is large if the measurement is $1.0 \text{ cm}$, but it is small if the measurement is $100 \text{ m}$. To give a more descriptive account of the uncertainty, fractional uncertainty or percent uncertainty is used. In this type of description, the uncertainty is divided by the actual measurement. Therefore, the length of the computer disk label could be expressed as

$$\ell = 5.5 \text{ cm} \pm \frac{0.1 \text{ cm}}{5.5 \text{ cm}} = 5.5 \text{ cm} \pm 0.018 \text{ (fractional uncertainty)}$$

or as

$$\ell = 5.5 \text{ cm} \pm 1.8\% \text{ (percent uncertainty)}$$

When combining measurements in a calculation, the percent uncertainty in the final result is generally larger than the uncertainty in the individual measurements. This is called propagation of uncertainty and is one of the challenges of experimental physics.

Some simple rules can provide a reasonable estimate of the uncertainty in a calculated result:

**Multiplication and division:** When measurements with uncertainties are multiplied or divided, add the percent uncertainties to obtain the percent uncertainty in the result.

Example: The Area of a Rectangular Plate

$$A = \ell w = (5.5 \text{ cm} \pm 1.8\%) \times (6.4 \text{ cm} \pm 1.6\%) = 35 \text{ cm}^2 \pm 3.4\%$$

$$= (35 \pm 1) \text{ cm}^2$$

**Addition and subtraction:** When measurements with uncertainties are added or subtracted, add the absolute uncertainties to obtain the absolute uncertainty in the result.

Example: A Change in Temperature

$$\Delta T = T_2 - T_1 = (99.2 \pm 1.5)\degree C - (27.6 \pm 1.5)\degree C = (71.6 \pm 3.0)\degree C$$

$$= 71.6\degree C \pm 4.2\%$$

**Powers:** If a measurement is taken to a power, the percent uncertainty is multiplied by that power to obtain the percent uncertainty in the result.
Example: The Volume of a Sphere

\[ V = \frac{4}{3} \pi r^3 = \frac{4}{3} \pi (6.20 \text{ cm } \pm 2.0\%)^3 = 998 \text{ cm}^3 \pm 6.0\% \]

\[ = (998 \pm 60) \text{ cm}^3 \]

For complicated calculations, many uncertainties are added together, which can cause the uncertainty in the final result to be undesirably large. Experiments should be designed such that calculations are as simple as possible.

Notice that uncertainties in a calculation always add. As a result, an experiment involving a subtraction should be avoided if possible, especially if the measurements being subtracted are close together. The result of such a calculation is a small difference in the measurements and uncertainties that add together. It is possible that the uncertainty in the result could be larger than the result itself!

Chapter 1

Answers to Quick Quizzes
(a) 
2. False
3. (b)

Answers to Odd-Numbered Problems
(a) $5.52 \text{ kg/m}$  (b) It is between the density of aluminum and that of iron and is greater than the densities of typical surface rocks.
3. 23.0 kg
5. 7.69 cm
9. (b) only
11. (a) kg m/s  (b) N s
13. No.
15. 11.4 kg/m
17. 871 m
19. By measuring the pages, we find that each page has area $0.277 \text{ m} \times 0.217 \text{ m} = 0.060 \text{ m}^2$. The room has wall area $37 \text{ m}^2$, requiring 616 sheets that would be counted as 232 pages. Volume 1 of this textbook contains only 784 pages.
21. 1.00
23. 4.05
25. 2.86 cm
27. 151
29. (a) 507 years  (b) 2.48 bills
31. balls in a room 4 m by 4 m by 3 m
33. piano tuners
35. (209 4) cm
37. 31 556 926.0 s

23. [Diagram with red lines and black dots]
25. (a) 4.98 s  (b) 1.20 m/s
27. (a) 9.00 m/s  (b) 3.00 m/s  (c) 17.0 m/s  (d) The graph of velocity versus time is a straight line passing through 13 m/s at 10:05 a.m. and sloping downward, decreasing by 4 m/s for each second thereafter.  
   (e) If and only if we know the object's velocity at one instant of time, knowing its acceleration tells us its velocity at every other moment as long as the acceleration is constant.
29. 16.0 cm/s
31. (a) 202 m/s  (b) 198 m
33. (a) 35.0 s  (b) 15.7 m/s
35. 3.10 m/s
37. (a)
(b) Particle under constant acceleration
(c)  \( \text{Equation 2.17} \)
(d)  
(e) 1.25 m/s    (f) 8.00 s
39. (a) The idea is false unless the acceleration is zero. We define constant acceleration to mean that the velocity is changing steadily in time. So, the velocity cannot be changing steadily in space.  
   (b) This idea is true. Because the velocity is changing steadily in time, the velocity halfway through an interval is equal to the average of its initial and final values.
41. (a) 13.5 m  (b) 13.5 m  (c) 13.5 m  (d) 22.5 m
43. (a) 1.88 km  (b) 1.46 km
45. (a) 0.231 m  (b) 0.364 m  (c) 0.399 m  (d) 0.175 m
47. David will be unsuccessful. The average human reaction time is about 0.2 s (research on the Internet) and a dollar bill is about 15.5 cm long, so David's fingers are about 8 cm from the end of the bill before it is dropped. The bill will fall about 20 cm before he can close his fingers.
49. (a) 510 m  (b) 20.4 s
51. 1.79 s
53. (a) 10.0 m/s up  (b) 4.68 m/s down

57. (a) 4.00 m/s  (b) 1.00 ms  (c) 0.816 m
59. (a) 10.0  3.00  (1.50  (In these expressions, is in m/s is in meters, and is in seconds.)  (b) 3.00 ms  (c) 450 m/s
61. (a) 4.00 m/s  (b) 1.00 ms  (c) 0.816 m
63. (a) 3.00 s  (b) 15.3 m/s
65. (a) 3.00 m/s down and 34.8 m/s down
67. (a) 2.85 s  (b) It is exactly the same situation as in Example 2.8 except that this problem is in the vertical direction. The descending elevator plays the role of the speeding car, and the falling bolt plays the role of the accelerating trooper. Turn Figure 2.13 through 90° clockwise to visualize the elevator–bolt problem!  
   (c) If each floor is 3 m high, the highest floor that can be reached is the 13th floor.
69. (a) From the graph, we see that the Acela is cruising at a constant positive velocity in the positive direction from about 50 s to 50 s. From 50 s to 200 s, the Acela accelerates in the positive direction reaching a top speed of about 170 mi/h. Around 200 s, the engineer applies the brakes, and the train, still traveling in the positive direction, slows down and then stops at 350 s. Just after
350 s, the train reverses direction (becomes negative) and steadily gains speed in the negative direction. (b) approximately 2.2 mi/h/s (c) approximately 6.7 mi

71. (a) Here, must be greater than and the distance between the leading athlete and the finish line must be great enough so that the trailing athlete has time to catch up.

(b) _______  (c) _______

73. (a) 5.46 s  (b) 73.0 m

(c) 13.0 m/s  (d) 26.7 m/s

75. (a) The velocity starts off larger than for small values of and then decreases, approaching zero as approaches 90°.

77. (a) 15.0 s  (b) 30.0 m/s  (c) 225 m

79. 1.60 m/s

81. (a) 35.9 m  (b) 4.91 s  (c) 45.8 m  (d) 22.6 m/s

85. (a) 26.4 m  (b) 6.8%

15. 55.1°

17. (a) 3.96 m/s horizontally forward (b) 9.6%

19. 67.8°

21. \( d \tan \theta_i - \frac{gt^2}{2v_i^2 \cos^2 \theta_i} \)

23. (a) The ball clears by 0.89 m. (b) while descending

25. (a) 18.1 m/s (b) 1.13 m (c) 2.79 m

27. 9.91 m/s

29. (a) (0, 50.0 m) (b) \(v_y = 18.0 m/s; v_x = 0 \) (c) Particle under constant acceleration (d) Particle under constant velocity (e) \( v_{fg} = v_x; v_{fv} = -gt \) (f) \( x_f = v_x t; y_f = y_i - \frac{1}{2} gt^2 \) (g) 3.19 s (h) 36.1 m/s, -60.1°

31. 1.92 s

33. 377 m/s^2

35. \(2.06 \times 10^3 \) rev/min

37. 0.749 rev/s

39. 7.58 \times 10^3 m/s, 5.80 \times 10^3 s

41. 1.48 m/s^2 inward and 29.0° backward

43. (a) Yes. The particle can be either speeding up or slowing down, with a tangential component of acceleration of magnitude \( \sqrt{b^2 - 4.5^2} = 3.97 m/s^2 \). (b) No. The magnitude of the acceleration cannot be less than \( v^2/r \) = 4.5 m/s^2.

45. (a) 1.26 h (b) 1.13 h (c) 1.19 h

47. (a) 15.0 km/h east (b) 15.0 km/h west

(e) 0.0167 h = 60.0 s

49. (a) 9.80 m/s^2 down and 2.50 m/s^2 south (b) 9.80 m/s^2 down (c) The bolt moves on a parabola with its axis downward and tilting to the south. It lands south of the point directly below its starting point. (d) The bolt moves on a parabola with a vertical axis.

51. (a) \( \frac{2d/c}{\sqrt{e^2 - v^2/c^2}} \) (b) \( \frac{2d/c}{\sqrt{e}} \)

(c) The trip in flowing water takes a longer time interval. The swimmer travels at the low upstream speed for a longer time interval, so his average speed is reduced below \( c \). Mathematically, \( 1/(1 - v^2/c^2) \) is always greater than 1. In the extreme, as \( v \rightarrow c \), the time interval becomes infinite. In that case, the student can never return to the starting point because he cannot swim fast enough to overcome the river current.

53. 15.3 m

55. 5.44 m/s^2

57. The relationship between the height \( h \) and the walking speed is \( h = (4.16 \times 10^{-3})v_x^2 \), where \( h \) is in meters and \( v_x \) is in meters per second. At a typical walking speed of 4 to 5 km/h, the ball would have to be dropped from a height of about 1 cm, clearly much too low for a person’s hand. Even at Olympic-record speed for the 100-m run (confirm on the Internet), this situation would only occur if the ball is dropped from about 0.4 m, which is also below the hand of a normally proportioned person.

59. (a) 101 m/s (b) 3.27 \times 10^4 ft (c) 20.6 s

61. (a) 26.9 m/s (b) 67.3 m (c) (2.06 \hat{i} - 5.00 \hat{j}) m/s^2

63. (a) \((7.62 \hat{i} - 6.48 \hat{j}) \) cm (b) \((10.0 \hat{i} - 7.05 \hat{j}) \) cm

65. (a) 1.52 km (b) 36.1 s (c) 4.05 km

67. The initial height of the ball when struck is 3.94 m, which is too high for the batter to hit the ball.

69. (a) 1.69 km/s (b) 1.80 h

71. (a) 46.5 m/s (b) -77.6° (c) 6.34 s

73. (a) \( x = v_x(0.164 3 + 0.002 299 v_x^2)^{1/2} + 0.047 94 v_x^2 \), where \( x \) is in meters and \( v_x \) is in meters per second (b) \( 0.041 0 m \) (c) 961 m (d) \( x = 0.405 v_x \) (e) \( x = 0.095 9 v_x^2 \) (f) The graph of \( x \) versus \( v_x \) starts from the origin as a straight line with slope 0.405 s. Then it curves upward above this tangent line, becoming closer and closer to the parabola \( x = 0.095 9 v_x^2 \), where \( x \) is in meters and \( v_x \) is in meters per second.

75. (a) 6.80 km (b) 3.00 km vertically above the impact point (c) 66.2°

77. (a) 20.0 m/s (b) 5.00 s (c) \((16.0 \hat{i} - 27.1 \hat{j}) \) m/s (d) 6.53 s (e) 24.5 \hat{i} m

79. (a) 4.00 km/h (b) 4.00 km/h

81. (a) 45.2 m (b) \((9.66 \hat{i} - 25.6 \hat{j}) \) m/s (c) Air resistance would ordinarily make the jump distance smaller and the final horizontal and vertical velocity components both somewhat smaller. If a skilled jumper shapes her body into an airfoil, however, she can deflect downward the air through which she passes so that it deflects her upward, giving her more time in the air and a longer jump.

83. (a) swim perpendicular to the banks (b) 133 m (c) 53.1° (d) 107 m

85. 33.5° below the horizontal

87. \( \tan^{-1} \left( \sqrt{\frac{2gh}{v}} \right) \)

89. Safe distances are less than 270 m or greater than 3.48 \times 10^3 m from the western shore.

Answers to Quick Quizzes and Odd-Numbered Problems

causing the acceleration of the 5-kg pair of objects. The acceleration is real and nonzero, but it lasts for so short a time that it is never associated with a large velocity. The frame of the building and your legs exert forces, small in magnitude relative to the hammer blow, to bring the partition, block, and you to rest again over a time interval large relative to the hammer blow.

85. (a) Upper pulley:   Lower pulley:

87. 0.287

89. (b) If is greater than tan \(1/\), motion is impossible.

91. (a) The net force on the cushion is in a fixed direction, downward and forward making angle tan \(\theta\) with the vertical. Starting from rest, it will move along this line with (b) increasing speed. Its velocity changes in magnitude. (c) 1.63 m (d) It will move along a parabola. The axis of the parabola is parallel to the line described in part (a). If the cushion is thrown in a direction above this line, its path will be concave downward, making its velocity become more and more nearly parallel to the line over time. If the cushion is thrown down more steeply, its path will be concave upward, again making its velocity turn toward the fixed direction of its acceleration.

Answers to Quick Quizzes

(i) (a) (ii) (b)

(i) Because the speed is constant, the only direction the force can have is that of the centripetal acceleration. The force is larger at than at because the radius at is smaller. There is no force at because the wire is straight. (ii) In addition to the forces in the centripetal direction in part (a), there are now tangential forces to provide the tangential acceleration. The tangential force is the same at all three points because the tangential acceleration is constant.

15. (a) — (b) 2

17. (a) 8.62 m (b) downward (c) 8.45 m/s (d) Calculation of the normal force shows it to be negative, which is impossible. We interpret it to mean that the normal force goes to zero at some point and the passengers will fall out of their seats near the top of the ride if they are not restrained in some way. We could arrive at this same result without calculating the normal force by noting that the acceleration in part (c) is smaller than that due to gravity. The teardrop shape has the advantage of a larger acceleration of the riders at the top of the arc for a path having the same height as the circular path, so the passengers stay in the cars.

19. No. The archeologist needs a vine of tensile strength equal to or greater than 1.38 kN to make it across.

53. (a) 1.59 m/s  (b) 53.1 rad/s

55. (a) 11.4 N  (b) 7.57 m/s²  (c) 9.53 m/s  (d) 9.53 m/s

57. (a) 2(Rg/3)³/²  (b) (4Rg/3)³/²  (c) (Rg)³/²

59. (a) 500 J  (b) 250 J  (c) 750 J

61. (a) 3gsinθ  (b) The acceleration of 3gsinθ for the hoop is smaller than that for the disk.  
   (c) 3tanθ

Chapter 11

Answers to Odd-Numbered Problems

1. (d)

3. (b)

5. (a) 30 N·m (counterclockwise)  
   (b) 56 N·m (counterclockwise)

7. 45.0°

9. (a) Fᵢ = F₅ + F₇  (b) no

11. 17.5 k kg·m²/s

13. m(uᵢ − wᵢ) k

15. (a) zero  (b) (−mᵥ₁^³ sin²θ cos θ /2g) k  
   (c) (−2mᵥ₁^³ sin²θ cos θ /g) k

(d) The downward gravitational force exerts a torque on the projectile in the negative z direction.

17. mR(ω cos (vt + R) + 1) k

19. 60.0 kg·m²/s

21. (a) −mg cos θ k  (b) The Earth exerts a gravitational torque on the ball.

23. 1.20 kg·m²/s

25. (a) 0.360 kg·m²/s  (b) 0.540 kg·m²/s

27. (a) 0.433 kg·m²/s  (b) 1.73 kg·m²/s

29. (a) 1.57 × 10⁸ kg·m²/s  (b) 6.26 × 10⁵ s = 1.74 h

31. 7.14 rev/min
33. (a) The mechanical energy of the system is not constant. Some chemical energy is converted into mechanical energy. (b) The momentum of the system is not constant. The turntable bearing exerts an external northward force on the axle. (c) The angular momentum of the system is constant. (d) 0.360 rad/s counterclockwise (e) 99.9 J

35. (a) 11.1 rad/s counterclockwise (b) No; 507 J is transformed into internal energy. (c) No; the turntable bearing imparts impulse 44.9 kg m/s north into the turntable–clay system and thereafter keeps changing the system momentum.

37. (a) down (b) /

39. (a) (b) No; some mechanical energy of the system changes into internal energy. (c) The momentum of the system is not constant. The axle exerts a backward force on the cylinder when the clay strikes.

41. (a) yes (b) 4.50 kg /s (c) No. In the perfectly inelastic collision, kinetic energy is transformed to internal energy. (d) 0.749 rad/s (e) The total energy of the system must be the same before and after the collision, assuming we ignore the energy leaving by mechanical waves (sound) and heat (from the newly-warmer door to the cooler air). The kinetic energies are as follows: 2.50 J; 1.69 J. Most of the initial kinetic energy is transformed to internal energy in the collision.

43. 5.46

45. 0.910 km/s

47. 7.50

49. (a) 7 /3 (b) mgd (c) 3 counterclockwise (d) /7 upward (e) mgd (f) 14gd (g) gd /21 (h) gd /21

51. (a) isolated system (angular momentum) (b) /2 (c) \( \tau \) - (d) \( \tau \) - (e) \( \frac{mv}{2} \) (f) \( -\frac{mv}{2} \) (g) \( \frac{mv}{2} \)

53. (a) \( \left( \frac{1}{2} J \right) \) (b) \( \frac{mv}{2} \) (c) \( \frac{mv}{2} \)

55. (a) 3 750 kg m /s (b) 1.88 kJ (c) 3 750 kg m /s (d) 10.0 m/s (e) 7.50 kJ (f) 5.62 kJ

57. (a) 2 (b) 2 /3 (c) 4 /3 (d) 4 (e) 26 /27 (g) No horizontal forces act on the bola from outside after release, so the horizontal momentum stays constant. Its center of mass moves steadily with the horizontal velocity it had at release. No torques about its axis of rotation act on the bola, so the angular momentum stays constant. Internal forces cannot affect momentum conservation and angular momentum conservation, but they can affect mechanical energy.

59. an increase of 6.368 % or 0.550 s, which is not significant

61. (a) - (b) - (c) - (d) \( \frac{18}{18} \)

71. (a) 45.0 or 55.0 Hz (b) 162 or 242 N
75. (a) 34.8 m/s (b) 0.986 m
77. 3.85 m/s away from the station or 3.77 m/s toward the station
79. 283 Hz
81. 407 cycles
83. (b) 11.2 m, 63.4°

Answers to Odd-Numbered Problems

(a) 106.7°F (b) Yes; the normal body temperature is 98.6°F, so the patient has a high fever and needs immediate attention.
3. (a) 109°F, 195 K (b) 98.6°F, 310 K
5. (a) 320°F (b) 77.3 K
9. (a) 0.176 mm (b) 8.78 m (c) 0.0930 cm
11. 3.27 cm
13. 1.54 km. The pipeline can be supported on rollers. Shaped loops can be built between straight sections. They bend as the steel changes length.
15. (a) 0.109 cm (b) increase
17. (a) 437°C (b) 2.1°C (c) No; aluminum melts at 660°C (Table 20.2). Also, although it is not in Table 20.2, Internet research shows that brass (an alloy of copper and zinc) melts at about 900°C.
19. (a) 99.8 mL (b) It lies below the mark. The acetone has reduced in volume, and the flask has increased in volume.
21. (a) 99.4 mL (b) 2.01 L (c) 0.998 cm
23. (a) 11.2 kg/m (b) 20.0 kg
25. 1.02 gallons
27. 4.28 atm
29. (a) 2.99 mol (b) 1.80 molecules
31. 1.50 molecules
33. (a) 41.6 mol (b) 1.20 kg (c) This value is in agreement with the tabulated density.
35. 3.55 L
37. (a) 3.95 atm 400 kPa (b) 4.43 atm 449 kPa
39. 473 K
41. 3.68 cm
43. 1.89 MPa
45. 6.57
47. (a) 2.542 cm (b) 300°C
49. 1.12 atm
51. 3.37 cm
53. 0.0942 Hz
55. (a) 94.97 cm (b) 95.03 cm
57. (b) As the temperature increases, the density decreases (assuming is positive). (c) 5 (°C) (d) 2.5 (°C)
59. (a) 9.5 s (b) It loses 57.5 s.
61. (b) It assumes is much less than 1.
63. (a) yes, as long as the coefficients of expansion remain constant (b) The lengths and at 0°C need to satisfy Then the steel rod must be longer. With 5.00 cm, the only possibility is 14.2 cm and 9.17 cm.
65. (a) 0.34%  (b) 0.48%  (c) All the moments of inertia have the same mathematical form: the product of a constant, the mass, and a length squared.
67. 2.74 m
69. (a) $\frac{gP}{\rho \cdot gh}$  (b) decrease  (c) 10.3 m
73. (a) 6.17 kg/m  (b) 652 N  (c) 580 N  (d) 192 Hz
75. No; steel would need to be 2.30 times stronger.
77. (a) 7.50 kJ  (b) 900 K  (c) 900 K
5. 0.845 kg
9. 88.2 W
11. 29.6°C
13. (a) 1822 J/kg °C  (b) We cannot make a definite identification. It might be beryllium.  (c) The material might be an unknown alloy or a material not listed in the table.
15. (a) 380 K  (b) 2.04 atm
17. 2.27 km
19. 16.3°C
21. (a) 0°C  (b) 114 g
23. (a) 0°C  (b) 17.2 L
25. 466 J
27. (a) (b) According to $\pi RV$, it is proportional to the square of the volume.
29. 1.18 MJ
31. Process
33. 720 J
35. (a) 0.0410 m  (b) 5.48 kJ  (c) 5.48 kJ
37. (a) 7.50 kJ  (b) 900 K
39. (a) 0.0486 J  (b) 16.2 kJ  (c) 16.2 kJ
41. (a) 9.08 kJ  (b) 9.08 kJ
43. (a) 6.45 W  (b) 5.57
45. 74.8 kJ
47. 3.49
49. (a) 1.19  (b) a factor of 1.19
51. 8.99 cm
53. (a) 1.85 ft °F h/Btu  (b) a factor of 1.78
55. 51.2°C
57. (a) W (b) K/s
59. (a) 6.08 J (b) 4.56
61. (a) 17.2 L (b) 0.351 L/s
63. 1.90 J/kg
65. (a) 9.31 J (b) 8.47 J (c) 8.38
67. (a) 13.0°C (b) 0.532°C/s
69. (a) 2.000 W (b) 4.46°C
71. 2.33 kg
73. (5.87 °C)
75. (a) 3.16 W (b) 3.17
(c) It is 0.408% larger.  (d) 5.78
77. 3.76 m/s
79. 1.44 kg
81. (a) 4.19 mm/s (b) 12.6 mm/s
83. 3.66 10.2 h

Chapter 20

Answers to Quick Quizzes

(i) iron, glass, water  (ii) water, glass, iron
2. The figure below shows a graphical representation of the internal energy of the system as a function of energy added. Notice that this graph looks quite different from Figure 20.3 in that it doesn’t have the flat portions during the phase changes. Regardless of how the temperature is varying in Figure 20.3, the internal energy of the system simply increases linearly with energy input; the line in the graph below has a slope of 1.

3. Situation  System  $Q$  $W$  $\Delta U$

| (a) Rapidly pumping up a bicycle tire | Air in the pump | 0 | + |
| (b) Pan of room-temperature water sitting on a hot stove | Water in the pan | -- | -- |
| (c) Air quickly leaking out of a balloon | Air originally in the balloon | -- | -- |

4. Path A is isovolumetric, path B is adiabatic, path C is isothermal, and path D is isobaric.

5. (b)

Answers to Odd-Numbered Problems

(a) 2.26 J  (b) 2.80 steps  (c) 6.99 steps

Diode(s), 1018

applications, 1018, 1018

circuit symbol for, 1018

t junction, 814, 814, 1365, 1365–1366, 1366

light-absorbing, 1366, 1367

light-emitting (LEDs), 1366, 1367

Dipole antennas, 1044

Dipole–dipole force, 1343

Dipole-induced dipole force, 1343

Dirac, Paul A. M., 1315, 1316, 1317, 1449, 1449

Dirac sea, 1449, 1449

Direct current (DC), 833

AC–DC converters, 1017, 1017, 1018, 1018–1019

disadvantages of, 1018

Direct-current (DC) circuits

circuit symbol for, 1018–1019

Kirchhoff’s rules, 843–846

problem-solving strategy for, 844–845

RC circuits, 846–852

resistors in parallel, 838, 838–840, 839, 840, 842–843

resistors in series, 836–837, 837, 839

RLC circuits, 984–986, 985, 986, 986

RL circuits, 972–976, 973, 973, 974, 975

time response of, 974

Direct-current (DC) generators, 951, 951–952

Direct-current (DC) power supply, 1018–1019

Direction of polarization, 1175

Direction of propagation, 1035

Disintegration energy (E), 1367

Displacement vector, 79

Displacement node, 547

Displacement vector, 79

Displacement node, 547

Displacement vector, 79

Displacement node, 547

Displacement vector, 79

Displacement node, 547

Displacement vector, 79

Dissociation energy, 1390

Dissociation energy, 1390

Diverging mirrors, 1095, 1095–1096

Diverging mirrors, 1095, 1095–1096
INDEX

Division
of fractions, A–6
of powers, A–6
in scientific notation, A–5
significant figures in, 12
and uncertainty, A–20

DNA molecules, hydrogen bonding in, 1344, 1344

Domains, in ferromagnetic material, 920–921, 921

Domain walls, 920
Donor atom, 1318, 1363, 1363
Doped semiconductors, 1363,
1363–1364, 1364

Doping, 1362
Doppler effect, 517, 517–521, 518, 519
relativistic, 1209–1210, 1471–1472
Doppler-shift expression, general, 519
Dot product. See Scalar product
Double-refracting materials, 1179,
1179–1180, 1179n, 1180
Double-slit diffraction patterns
light intensity distribution,
1164–1165, 1165
position of fringes, 1165, 1165

Double-slit interference patterns,
1134–1142, 1135, 1136, 1142
conditions for interference, 1136
in electron beams, 1255,
1255–1256, 1256
light intensity distribution,
1140–1142, 1142
position of fringes, 1137, 1137–1140
Young’s double-slit experiment,
1134–1137, 1135, 1136, 1137

Doublet, 1314–1315
Down quark (d), 6, 7, 1462, 1463t, 1464t
Drag, 434, 434. See also Air resistance
Drag coefficient (D), 164, 167
Drag racing, 21

Drain, of field-effect transistor, 1368, 1368
Drift speed (vD), 810, 810–811, 816, 891
Drift velocity (vD), 810, 810, 817
Drude, Paul, 816
Drude model of electrical conduction,
816–818

Dynamics. See also Laws of motion
fluid, 427–434
rotational, 385

Dynode, of photomultiplier tube, 1245

ε (Euler’s number), 163, A–9
ε (fundamental charge), 692, 694,
764–765
ε0 (permittivity of free space), 694

Ears. See Hearing
Earth
centrifugal acceleration of, 93–94
density of, 392
escape speed, 405t, 641–642
as inertial frame, 114
kinetic energy of, 189t

to resistor, 821–823, 834–836,
842–843, 852, 1001, 1012
transmission of, 822, 1015, 1017,
1017–1018
corona discharge in, 763–764,
766, 766
as energy transfer, 212, 213
and F2R loss, 822, 822
units of, 232

Electrical safety, in household wiring,
853–855, 854

Electrical systems, analogies with
mechanical systems, 980–982,
981, 984–985, 985t

Electrical transmission, 1015, 1017,
1017–1018
corona discharge in, 763–764, 766,
766 as energy transfer, 212, 213
F2R loss in, 822, 822

Electric charge. See Charge
Electric current. See Current
Electric dipole, 701
in electric field, 793, 793–795
electric field lines of, 710, 710
electric field of, 702–703, 755, 756
electric potential around, 758
equipotential surfaces for, 755, 756
Electric dipole moment (μ), 793,
793–794

Electric field (E), 699
in capacitor, 750–751, 751,
795–796, 796
of conductor
in cavities, 763, 763
and corona discharge, 763–764,
766, 766
as conservative field, 752
of continuous charge distribution,
704, 704–708
and current density, 812
determining, using Gauss’s law,
730–735
direction of, 700, 700–701
due to point charges, 752–754, 753
direction of, 700–703, 755, 756
electric dipole in, 793, 793–795
electric potential density of, 788,
1040–1041
electric force density of, 788, 1040–1041
of finite group of point charges, 701
vs. gravitational fields, 749, 749
induced by magnetic flux change,
947, 947–949

Lorentz force and, 880
vs. magnetic field, 905–906
motion of charged particle in (uniform
field), 710–713
particle in a field model, 699, 699–703,
700, 701
problem-solving strategy for, 705
as rate of change of electrical
potential, 748
of sinusoidal electromagnetic wave,
1035, 1035–1039, 1036,
1041–1042
superposition principle for, 701, 702–703
units of, 748
value of, from electric potential, 755, 755–756
work done by, 747–748, 750, 752–754
Electroweak theory, 1467–1468
Elements. See also Periodic table of the elements
absorption spectroscopy of, 1297–1298, 1298
ionization energy vs. atomic number, 1321, 1321–1322
origin of, 1387
Ellipse, 395, 395, A–10, A–10
Elliptical orbits, 395–396, 396, 403
cmf (E), 833–836, 834
back, 952–953, 971, 973
induced, 935–939, 936, 937, 938, 970
(See also Induction)
motional, 939–944, 940, 941, 942, 944–947, 945–947
self-induced, 970–971, 972
Emissions
line width of, 1258
spontaneous, 1325, 1325
stimulated, 1325–1327, 1326
Emission spectroscopy, 1297–1299, 1299, 1299–1322, 1325
Emissivity (ε), 615, 1284–1285
Endothermic reactions, 1405
Energetically favorable bonds, 1342
Energy (E), 177–201. See also Conservation of energy; Internal energy; Kinetic energy (K); Potential energy
atomic cohesive
of covalent solids, 1355, 1355
of ionic solids, 1353
in capacitor, 786, 786–790, 787, 976
carried by electromagnetic waves, 1039–1042
as currency of nature, 214
dark, in Universe, 1474
definition of, 177
electrical, mechanical analogies to, 980–982, 981, 984–985, 985
entropy and, 672
equation partition theorem for, 630, 635–637
in inductor, 976–978
ionic cohesive, of ionic solids, 1353
in L.C circuit, 976–978, 983, 983–984
mass as form of, 1217–1220
mechanical (E_mech), 198, 216
conservation of, 198, 216–217, 218, 221, 314
nonconservative forces and, 227–231
in simple harmonic motion, 458–461, 459, 460
total, in orbits, 403
transformation into internal energy, 196, 196–197, 216–217, 222–224, 227–231
in mechanical waves, 212, 213, 484, 495, 495–497
phase change and, 597–600, 599
planetary and satellite motion and, 402–407
quantization of. See Energy levels;
Quantum mechanics of quantum particle in a box, 1273, 1273–1274, 1274, 1276–1277
relativistic, 1216–1220, 1217
and resistor delivered, 820–821, 851–852, 1001
stored, 976
and rolling motion, 318–321
and rotational motion, 312–316, 318–321
in simple harmonic motion, 458–461, 459, 460
spreading, and entropy, 672
transfer mechanisms for, 212, 212–213, 569, 594, 603, 603–604
in thermal processes, 608–614
transformation mechanism for, 197
units of, 232, A–2
in work as transfer of, 180, 190, 212, 212
conversion mechanism for, 197
in adiabatic free expansion, 672, 674, 674–676, 677
Carnot engine and, 673–674, 677–678
change in, and energy spreading, 672
change in, for thermodynamic systems, 671–678
choice, of microstates, 668–671
history of concept, 667–668
missing information, of microstates, 668–671
probability, of microstates, 668–671
in reversible and irreversible processes, 672–678
and second law of thermodynamics, 672–678
as state variable, 667, 676
thermal conduction and, 674–675, 677
for thermodynamic systems, 670–671
uncertainty, of microstates, 668–671

γ-intercepts, A–8, A–8, A–10, A–10
Y meson, 1464
Young, Thomas, 1059, 1134, 1138 Young’s modulus (Y), 373–374, 374t Yukawa, Hideki, 1451, 1451–1452, 1453 Z bosons, 1448, 1449t, 1453, 1454, 1467–1468, 1468 Zee effect, 1313, 1313–1314 Zero absolute, 572 as significant figures, 12 Zeroth law of thermodynamics, 568–570, 569, 569 Zeroth-order maximum, 1138, 1170 Zinc (Zn) isotopes, 1397t work function of, 1243t Zweig, George, 1462, 1463
Conversions

Length
1 in. = 2.54 cm (exact)
1 m = 39.37 in. = 3.281 ft
1 ft = 0.3048 m
12 in. = 1 ft
3 ft = 1 yd
1 yd = 0.9144 m
1 km = 0.621 mi
1 mi = 1.609 km
1 µm = 10⁻⁶ m = 10⁵ nm
1 light-year = 9.461×10¹⁵ m

Area
1 m² = 10⁴ cm² = 10.76 ft²
1 ft² = 0.0929 m²
144 in.² = 1 in.²

Volume
1 m³ = 10⁶ cm³ = 35.3 ft³
1 ft³ = 1.728 in.³
1 gal = 3.786 L

Mass
1 000 kg = 1 t (metric ton)
1 slug = 14.59 kg
1 u = 1.66×10⁻²⁷ kg = 931.5 MeV/c²

Force
1 N = 0.224 8 lb
1 lb = 4.448 N

Velocity
1 mi/h = 1.47 ft/s = 0.447 m/s = 1.61 km/h
1 m/s = 100 cm/s = 3.281 ft/s
1 mi/min = 60 mi/h = 88 ft/s

Acceleration
1 m/s² = 3.28 ft/s² = 100 cm/s²
1 ft/s² = 0.304 8 m/s² = 30.48 cm/s²

Pressure
1 bar = 10⁵ N/m² = 14.50 lb/in.²
1 atm = 760 mm Hg = 76.0 cm Hg
1 atm = 14.7 lb/in.² = 1.013×10⁵ N/m²
1 Pa = 1 N/m² = 1.45×10⁻⁴ lb/in.²

Time
1 yr = 365 days = 3.16×10⁷ s
1 day = 24 h = 1.44×10⁵ min = 8.64×10⁴ s

Energy
1 J = 0.738 ft·lb
1 cal = 4.186 J
1 Btu = 252 cal = 1.054×10⁵ J
1 eV = 1.602×10⁻¹⁹ J
1 kWh = 3.60×10⁶ J

Power
1 hp = 550 ft·lb/s = 0.746 kW
1 W = 1 J/s = 0.738 ft·lb/s
1 Btu/h = 0.293 W

Some Approximations Useful for Estimation Problems

<table>

### Mathematical Symbols Used in the Text and Their Meaning

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>=</td>
<td>is equal to</td>
</tr>
<tr>
<td>=</td>
<td>is defined as</td>
</tr>
<tr>
<td>≠</td>
<td>is not equal to</td>
</tr>
<tr>
<td>∝</td>
<td>is proportional to</td>
</tr>
<tr>
<td>~</td>
<td>is on the order of</td>
</tr>
<tr>
<td>&gt;</td>
<td>is greater than</td>
</tr>
<tr>
<td>&lt;</td>
<td>is less than</td>
</tr>
<tr>
<td>&gt;&gt; (&lt;&lt;)</td>
<td>is much greater (less) than</td>
</tr>
<tr>
<td>≈</td>
<td>is approximately equal to</td>
</tr>
<tr>
<td>Δx</td>
<td>the change in x</td>
</tr>
<tr>
<td>Σ</td>
<td>the sum of all quantities x, from i = 1 to i = N</td>
</tr>
<tr>
<td></td>
<td>x</td>
</tr>
<tr>
<td>Δx → 0</td>
<td>Δx approaches zero</td>
</tr>
<tr>
<td>dx</td>
<td>the derivative of x with respect to t</td>
</tr>
<tr>
<td>∂x</td>
<td>the partial derivative of x with respect to t</td>
</tr>
<tr>
<td>∫</td>
<td>integral</td>
</tr>
</tbody>
</table>
